1. The presentation and treatment of acute and chronic bromocriptine toxicity are similar to that of other ergot alkaloids and include delirium, hallucinations, vasospastic crisis, and retroperitoneal/pulmonary fibrosis.

Catechol-O-Methyltransferase Inhibitors

Because levodopa is metabolized in the periphery by COMT to the inactive metabolite 3-OMD, the addition of the reversible COMT inhibitors tolcapone (Tasmar[®]) or entacapone (Comtan[®]) to Parkinson disease treatment regimens has provided effective adjuncts to levodopa therapy [2]. These medications also decrease formation of 3-OMD, which, at least theoretically, competes with levodopa for transport to the brain [2].

Pharmacokinetics

Tolcapone is absorbed rapidly from the gastrointestinal tract, with an elimination half-life of 2–3 h, and is >99.9% protein-bound. It is metabolized nearly completely by the liver with little parent drug excreted in the urine [55]. Interaction between tolcapone and other highly protein-bound medications has not been definitively demonstrated.

Entacapone is readily absorbed and is predominantly protein-bound (98%). The drug is also nearly completely hepatically metabolized, and small amounts of unchanged drug are found in the urine [56]. Similar to tolcapone, no significant interactions have been shown between entacapone and other protein-bound medications.

Catechol-O-Methyltransferase Inhibitors**Tolcapone (Tasmar)**

Volume of distribution: 0.10–0.14 L/kg

Protein binding: 99.9%

Metabolites: 3-*O*-methyl-tolcapone (>90%)

Plasma elimination half-life: 2–3 h

Entacapone (Comtan)

Volume of distribution: 0.24–0.56 L/kg

Protein binding: 98%

Metabolites: entacapone glucuronide (>90%)

Plasma elimination half-life: 0.4–0.7 h

Clinical Presentation**Adverse Effects**

Side effects of the COMT inhibitors are similar to those of levodopa and are related to increased levodopa availability. Severe and explosive diarrhea has been reported in approximately 5–10% of patients at therapeutic doses [2]. Harmless discoloration of urine also may occur. One potentially significant adverse effect of tolcapone is hepatotoxicity, an idiosyncratic effect found to occur in approximately 1–3% of patients taking this drug [2, 57]. The mechanism of liver injury seems to involve mitochondrial dysfunction [58]. Four cases of fulminant liver failure have been reported secondary to tolcapone, and, as a result, a “black box” warning has been issued in regard to this medication in the United States. Tolcapone is not available in Europe or Canada but can be obtained in the United States. Entacapone has not been associated with liver dysfunction [2].

Overdose and Toxicity

There are no reported human cases of overdose with either tolcapone or entacapone. Studies performed on healthy individuals taking larger-than-recommended daily amounts of both drugs resulted in minor symptoms that readily resolved on discontinuation of the medication. Theoretically, coadministration of a COMT inhibitor and

MAO inhibitor could result in central and peripheral catecholamine excess, presenting clinically as a sympathomimetic poisoning syndrome.

Diagnosis and Treatment**Indications for ICU Admission****in Antiparkinsonian Drug Toxicity****Catechol-O-methyltransferase inhibitors**

For signs of sympathomimetic toxicity, see ► Chap. 25, “Sympathomimetic Syndrome”.

No specific diagnostic tests are indicated in the setting of COMT inhibitor overdose. The emphasis of treatment should be on supportive care.

Key Points in the Evaluation and Treatment of Antiparkinsonian Drug Toxicity**COMT Inhibitors**

1. Chronic, dose-related adverse effects of COMT inhibitor treatment are similar to those of levodopa.
2. Hepatic toxicity is associated with tolcapone use.
3. Toxic interactions between COMT and MAO inhibitors are likely.

COMT, catechol-*O*-methyltransferase;
MAO, monoamine oxidase

Neuroprotective Agents

A broad variety of medications are aimed at protecting or preserving healthy striatal neurons in patients with Parkinson disease. These neuroprotective agents include free radical scavengers, iron chelators (e.g., deferoxamine), nitric oxide synthesis inhibitors, calcium channel blockers, anti-inflammatories, steroids, trophic factors, and antiapoptotic medicines. Many of

these agents, such as calcium channel blockers and deferoxamine, are discussed elsewhere in this text.

In the central nervous system, γ -aminobutyric acid (GABA) is the main inhibitory neurotransmitter. Three major GABA receptors – GABA_A, GABA_B, and GABA_C – have been identified. Baclofen (β -(4-chlorophenyl)- γ -aminobutyric acid) is a GABA agonist, specific to GABA_B at therapeutic doses, that has been used to treat spasticity of various etiologies (e.g., multiple sclerosis, paraplegia, quadriplegia, cerebral palsy). It has also been used off-label for dystonia, jerking, restless legs, chorea, stiff-person syndrome, torticollis, tetanus, hiccups, trigeminal neuralgia, cluster headaches, and musculoskeletal pain; with more recent investigations for the management of rumination, supragastric belching, and gastroesophageal reflux; alcohol, opioid, and cocaine abuse disorders; bladder spasm; and in combined use with antimuscarinic agents for overactive bladder [1–28].

Recently, elevated doses of baclofen (up to 300 mg/day) were prescribed to treat craving in alcoholic patients, following the self-experience reported by a French physician [29]. This protocol is based on animal studies showing that, in contrast to other therapies, increasing doses of baclofen are able not only to reduce but also to suppress craving in animals chronically intoxicated with ethanol. Several RCTs are ongoing to demonstrate whether these elevated doses are efficient or not. This experience led to the development of severe poisonings due to the huge presumed ingested doses [30–32].

Biochemistry, Pharmacology, and Pathophysiology

Baclofen is a structural analogue of GABA (Fig. 1) [33].

Pharmacokinetics

Baclofen is absorbed rapidly after oral administration, with a bioavailability of 70–85%. However, its central nervous system penetration is more limited, sometimes requiring relatively large oral doses to achieve therapeutic effects. Oral baclofen has a low therapeutic index, primarily because it is distributed evenly between spinal and supraspinal levels after oral administration. Peak blood concentrations occur 1–3.5 h after therapeutic ingestion; however, after overdose, absorption is prolonged and incomplete. Although signs and symptoms of toxicity can begin shortly after overdose, resolution can be protracted. After intrathecal or oral overdose, it may take days for the patient to become fully alert. Elimination of this moderately lipophilic GABA agonist from nerve and brain tissue is much slower than from serum, explaining the persistence of effects despite undetectable serum baclofen concentrations. Baclofen is excreted primarily by glomerular filtration, and its clearance is proportional to creatinine clearance. Generally, 50–85% of an ingested dose is eliminated unchanged in urine within 72 h. The remaining 15% is deaminated to β -(*p*-chlorophenyl)- γ -hydroxybutyric acid. However, large inter-individual variability has been observed in both elimination

and oral absorption processes [5, 15, 27, 33–50]. In addition, in large ingestions, there may be a delayed rebound in plasma concentration, and this can be associated with recurrence of effect [51–53].

Pharmacokinetics of Baclofen Poisoning

Protein binding: 30–35%

Volume of distribution: 0.8–2.6 L/kg

Serum half-life: 2–8 h (longer after overdose and renal insufficiency)

Mechanism of clearance: primarily renal

GABA_B Receptors and the Pathophysiology of Toxic Effects

GABA_B receptors are expressed widely in the brain and the spinal cord, including the cerebral hemispheres, diencephalon, brainstem, and dorsal horn of the spinal cord. The GABA_B receptor comprises two subunits and is coupled to G proteins. Activation of these receptors promotes a decline in calcium conductance and intracellular cyclic adenosine monophosphate production.

Baclofen binds to presynaptic and postsynaptic GABA_B receptors (Fig. 2). Presynaptic receptor binding of GABA or baclofen hyperpolarizes presynaptic terminals by closing calcium channels and decreases neurotransmitter (e.g., catecholamines, glutamate, substance P) vesicle release from excitatory spinal pathways Fig. 2b), producing an inhibitory effect. Presynaptic binding also occurs at GABAergic autoreceptors, hyperpolarizing presynaptic terminals and decreasing

Fig. 1 Chemical structures of γ -aminobutyric acid (GABA) and baclofen. Baclofen is a GABA analogue containing a *para*-chlorophenyl moiety in the β position relative to the carboxylate

Fig. 2 Binding of γ -aminobutyric acid (GABA) and baclofen to GABA_B receptors. **(a)** GABA is released from presynaptic GABAergic neurons and may bind to GABA_B receptors on postsynaptic neurons, resulting in hyperpolarization of postsynaptic neurons. This has an inhibitory effect on the nervous system. GABA released from presynaptic GABAergic neurons also acts at GABA_B receptors on the presynaptic neurons, resulting in

decreased release of GABA from the neuron or autoregulation. This has an excitatory effect. **(b)** GABA_B receptors also are located on presynaptic neurons that release excitatory neurotransmitters. When GABA binds to these receptors, the release of excitatory neurotransmitters is diminished. This has an inhibitory effect. Baclofen can bind at all of these GABA_B receptors and produces an effect similar to that of GABA binding

GABA release (Fig. 2a), producing an excitatory effect. Postsynaptic binding to the GABA_B receptor hyperpolarizes the neuron via two separate actions, opening slow potassium channels and inhibiting dendritic calcium influx channels, and results in inhibition by creating a net negative membrane potential (see Fig. 2a). Inhibitory and excitatory effects may occur with the binding of baclofen to GABA_B receptors. Generally, when used therapeutically, the inhibitory effects prevail. The dual inhibitory and excitatory actions provide an explanation for the significant overlap of clinical manifestations (e.g., seizures) seen with overdose and withdrawal from baclofen.

Baclofen depresses γ and α motor neurons and inhibits monosynaptic extensor and polysynaptic flexor spinal reflexes. This activity accounts for the decreased muscle tone and the efficacy of

baclofen in treating spasticity. Baclofen affects afferent depolarization in the dorsal horn of the spinal cord and modulates nociceptive input from primary afferent fibers to neurons of the spinothalamic tract. This effect, along with the inhibition of substance P release, accounts for the efficacy of baclofen in the treatment of pain. Central and peripheral GABA receptors also are known to play a role in regulation of body temperature; this may account for the hypothermia generally seen after overdose and the hyperthermia generally seen in withdrawal from baclofen. Central nervous system depression secondary to baclofen may be attributed to stimulation of GABA_B receptors in the hippocampus, whereas respiratory and cardiovascular depression may result from stimulation of GABA_B receptors in the brainstem [6, 28, 33, 47, 54–62].

Clinical Presentation

Routes of Exposure

Oral

Acute ingestions of 300–970 mg in adults can be expected to produce serious intoxications, and doses of 1250–2500 mg have been fatal in adults [27]. Additionally, a retrospective database review of 23 cases of baclofen poisoning demonstrated baclofen ingestions of 200 mg or greater were predictive of more severe clinical manifestations and prolonged hospital stay than ingestions less than 200 mg [63]. Baclofen abuse has been reported in persons with a history of substance abuse and in adolescents seeking intoxication [64–66].

Intrathecal

Intrathecal administration is accomplished by a pump with a reservoir that is implanted surgically in the subcutaneous tissue of the abdominal wall. A catheter is threaded into the intrathecal space, allowing direct delivery into the cerebrospinal fluid. Complications include mechanical problems (dislodgement, disconnection, kinking, blockage), pump failure, and infection [33, 67–85]. In an 8-year study of 30 patients, the overall incidence of pump complications was 62%. The most frequent complication was catheter disconnection, followed by retraction of the intrathecal catheter [81]. Borrini and colleagues [70] attempted to assess the frequency and characterize complications related to intrathecal baclofen pump therapy in a cohort of 158 adult patients who were implanted before and during 2010. During 1 year of follow-up, the rate of adverse events was 0.023 per month, with 29% of cases related to the device and predominantly involving catheter dysfunctions [70]. Also, in a multicenter Japanese study of 400 patients with intrathecal baclofen pumps, catheter problems (migration, obstruction, kinking, and dislodgement) were observed in 8.5% of patients, pump malfunction in 1.8% of patients, and device-related and surgical wound infections in 3% of patients [86]. A study of 100 children and young adults demonstrated more frequent device-related complications in

those implanted with pumps with catheter access ports [78]. Separate from mechanical complications, intrathecal overdose has been reported in continuous infusion and after bolus injection [46, 56, 61, 87, 88].

Other Routes

Baclofen has also been used in topical formulations for the treatment of neuropathic pain; trialed in intravesical administration for bladder spasm; and proposed for subcutaneous, intravenous, and intraventricular delivery [17, 25, 35, 89, 90].

Clinical Manifestations of Baclofen Poisoning

Lee and colleagues [58] attempted to differentiate between acute and chronic baclofen poisonings, suggesting that acutely poisoned patients are more likely to present with encephalopathy (disturbances of consciousness or seizure or both), respiratory depression, muscular hypotonia, and generalized hyporeflexia. Chronically poisoned patients are more likely to present with hallucinosis, impaired memory, catatonia, or acute mania [58]. The same authors also noted that the acute intoxication syndrome has a faster onset, a shorter duration, more severe clinical manifestations, and a higher incidence of seizures compared with the chronic intoxication syndrome [58]. However, there is significant overlap in the clinical presentations of acute and chronic toxicity, as well as with the presentation of withdrawal, as discussed later.

Acute and Life Threatening Presentations

Neurologic. Headache, dizziness, incoordination, ataxia, myoclonus, fatigue, weakness, areflexia, flaccid extremities, encephalopathy, coma, and seizures, including status epilepticus, may occur [5, 27, 46, 47, 50, 56, 58, 61–66, 75, 88, 91–99]. The clinician needs to be aware of the risk of nonconvulsive (akinetic) status epilepticus [64, 97, 100]. Although baclofen has antiepileptic properties at low concentrations, it is proepileptic at high concentrations [56, 61, 96, 101]. Delayed psychosis and confusion with hallucinations have

been reported during the recovery phase [56, 63, 65, 95].

Pulmonary. Respiratory depression and failure may occur [5, 27, 46, 50, 56, 65, 75, 87, 91, 92, 95, 98, 102–105].

Cardiovascular. Hypertension or hypotension and tachycardia or bradycardia may occur. Tachycardia may alternate abruptly with bradycardia. Conduction abnormalities (including prolonged QT_c and first-degree heart block), premature atrial and ventricular contractions, supraventricular tachycardia, atrial flutter, and atrial fibrillation have been reported [5, 27, 46, 50, 56, 63, 65, 66, 75, 88, 95, 97–99, 103, 104].

Gastrointestinal. Nausea and vomiting may occur [5, 66, 91, 99, 103].

Ocular. Blurred vision, horizontal or vertical nystagmus, unreactive pupils, absent corneal reflexes, and absent doll's eye reflexes may occur. Pupils may be small or large [27, 50, 56, 58, 61, 63, 66, 92, 95–97, 103, 104].

Other. Hypothermia and hypersalivation may occur [27, 58, 66, 88, 97, 103]. Hyperthermia is reported rarely [58, 99] and is more likely to occur in baclofen withdrawal.

Chronic Intoxication

Toxicity can occur gradually after long-term intrathecal or oral dosing, especially in patients with concomitant renal insufficiency. Chronic intoxication may present with impaired memory, acute mania or catatonia, and hallucinosis; this has been called *chronic baclofen intoxication syndrome* [27, 58, 97]. Respiratory depression, apnea, bradycardia, tachycardia, hypotension, hypertension, tremor, weakness, hypotonia, areflexia, urinary retention, sedation, coma, seizures, orofacial dyskinesia, and hypothermia also have been reported as manifestations of chronic baclofen toxicity [15, 43, 48, 58].

Side Effects with Long-Term Use

Nausea, lightheadedness, vertigo, fatigue, drowsiness, confusion, and lethargy may occur as side effects of oral baclofen, owing to the narrow therapeutic margin [5, 48, 58, 61]. Occasionally, hypotension also is seen [48]. Other pharmacological complications of chronic baclofen use, particularly intrathecal use, have also been reported and

include: hypotonia, sexual dysfunction in males, constipation, and drug tolerance [106, 107].

Coma and the Diagnosis of Brain Death

Deep coma and brainstem dysfunction may mimic brain death in patients with severe baclofen poisoning. Despite these findings, patients with baclofen poisoning may survive neurologically intact if aggressive supportive care is provided. The diagnosis of brain death should be made extremely cautiously in patients with suspected baclofen toxicity. The American Academy of Neurology practice standards require the documentation of a proximate and irreversible neurologic injury prior to initiation of the brain death examination [108]. Several days of intensive care, serial neurologic examinations, and imaging studies to demonstrate irreversible brain injury should be pursued before pronouncing brain death in these patients [95]. Recovery has been reported after 5–7 days of coma [109]. A more detailed discussion of brain death determinations in this setting can be found in ► Chap. 13, “Poisoning Fatalities”.

Clinical Manifestations of Baclofen Withdrawal

Baclofen withdrawal may occur after diminished or discontinued oral administration or more commonly after intrathecal pump malfunction [5, 68, 76, 79, 82, 83, 110–113]. Withdrawal may occur shortly after recovery from baclofen toxicity when baclofen treatment is not reinitiated promptly in the long-term use [50, 104]. The withdrawal syndrome occurs within 12–96 h after cessation of use, and symptoms generally resolve within 24–72 h of resumption of treatment, although some improvement may be seen sooner [50, 72, 114].

Respiratory distress, tachypnea, hypotension or hypertension, bradycardia or tachycardia, dysrhythmias, heart block, sleeplessness, agitation, shaking, coma, areflexia, diplopia, dyskinesia, visual disturbances, loss of pupillary light and oculocephalic reflexes, hyperthermia, diaphoresis, and hypersalivation have been reported [5, 50, 57, 61, 67, 68, 71, 79, 83, 104, 110–112,

114–119]. Rhabdomyolysis, disseminated intravascular coagulation, renal failure, hepatic failure, cerebral ischemia, and brain death may ensue [57, 82, 115, 117, 119]. Elevations in liver transaminase, creatinine, creatine phosphokinase, white blood cell count, and prothrombin time levels have been reported [57, 113, 115]. Acidosis may occur [115]. Cases of reversible cardiomyopathies in the setting of baclofen withdrawal have also been reported [120, 121]. There is significant overlap in the clinical presentation of overdose and withdrawal (e.g., autonomic instability, coma, seizures, laboratory abnormalities), and differentiating between the two entities may be difficult [50]. One helpful clue is that spasticity and muscle spasms (likely to some degree an unmasking of an underlying condition) and hyperthermia are seen more commonly with withdrawal, whereas hypothermia and hypotonia is seen more commonly with overdose.

Baclofen withdrawal syndrome may appear clinically similar to benzodiazepine or ethanol withdrawal, serotonin syndrome, sympathomimetic syndrome, neuroleptic malignant syndrome, infection, other febrile illnesses, or multiorgan system dysfunction of other etiology [21, 57, 72, 113, 117, 119, 122, 123]. Infection of the pump pocket, meningitis, and sepsis must be considered in patients receiving intrathecal baclofen [57, 81, 83, 122]. Modern pumps have bacterial filters that generally prevent overwhelming intrathecal infection; however, infection still may occur [77, 81, 85]. Pump function can be assessed using computer program systems and by aspirating and measuring the amount of drug remaining in the system [57, 81, 119]. These maneuvers may help differentiate among withdrawal, toxicity, and infection [119].

Diagnosis

Laboratory Studies

Baclofen can be detected by gas chromatography–mass spectrometry and high-performance liquid chromatography [43, 45, 48, 64, 66, 93].

Plasma, rather than cerebrospinal fluid, concentrations generally are assessed [43]. In nonfatal overdose, plasma or serum concentrations of 0.5–15 mg/L have been reported [124]. In a single fatal overdose, the serum concentration was 17 mg/L [41]. Other laboratory abnormalities in poisoning may include elevated creatine phosphokinase, lactate dehydrogenase, glutamic oxaloacetic transaminase, alkaline phosphatase, amylase, blood glucose, and white blood cell count [45, 58, 97]. Analysis of cerebrospinal fluid should be considered to rule out other disease processes (e.g., meningoencephalitis).

Imaging Studies

Intrathecal pump systems are radiopaque. Radiographs may show loss of catheter integrity [76, 117, 119]. Imaging of the brain and spinal cord should be considered to rule out other disease processes (e.g., hemorrhage or infarction). Brain imaging is of particular importance when seizure occurs with focal-onset features.

Special Studies

Electroencephalography often reveals reversible abnormalities. Typical electroencephalography findings are diffuse slowing of background activity and burst suppression [56, 58, 61, 66, 94]. In more severe cases, periodic delta and triphasic waves and generalized epileptiform discharges suggestive of seizures are seen [47, 56, 58, 73, 94, 96]. Although some patients with severe baclofen toxicity may appear severely neurologically impaired by clinical and electroencephalography findings, these patients frequently recover fully with adequate supportive care.

Treatment

Generally, patients do well with aggressive supportive care. Fatalities have occurred, however, despite medical care [9, 45, 65]. Respiratory failure and deep coma should be managed promptly

and aggressively with intubation and mechanical ventilation.

Gastrointestinal Decontamination

Because of the rapid onset of coma, induction of emesis is not recommended. It is reasonable to administer oral activated charcoal without gastric lavage to patients with suspected ingestion of baclofen if an intact airway can be ensured [65]. The administration of activated charcoal has not been shown to alter the outcome of baclofen-poisoned patients, however. Administration of oral activated charcoal to patients who may develop a decrease in their level of consciousness should always be done cautiously. It is likely that any potential benefit of activated charcoal decreases as the time from ingestion increases, although delayed administration may be beneficial in the presence of documented persistent absorption [51] [Level III].

Cerebrospinal Fluid Removal

If a large bolus of baclofen accidentally is injected intrathecally, some cerebrospinal fluid may be removed immediately in an attempt to limit toxicity [56, 96, 98, 99, 125, 126] [Level III].

Extracorporeal Removal

Case series data indicate that duration of toxicity in patients with severe renal impairment may be shortened by hemodialysis [36, 127, 128] [Level III]. In contrast, in patients with normal renal function, hemodialysis seems not to modify the elimination half-life [51].

Specific Nonantidotal Treatments

Cardiovascular

Severe hypertension should be treated with short-acting agents because hypertension can

deteriorate rapidly to hypotension. If hypotension is unresponsive to intravenous fluid administration, vasopressor (e.g., norepinephrine) administration may be necessary [50, 56, 117]. Symptomatic bradycardia may respond to atropine [50, 65, 103, 105, 129] [Level III].

Indications for ICU Admission in Baclofen Poisoning

Evidence of toxicity after acute ingestion
Evidence of toxicity after recent pump adjustment or filling of reservoir
Evidence of significant toxicity after chronic exposure
Evidence of withdrawal symptoms after cessation of baclofen
Evidence of withdrawal symptoms with suspected pump failure

Neurologic

Seizures occur with baclofen toxicity and withdrawal. These seizures generally are brief and respond readily to treatment [65, 88]. Benzodiazepines have been used to control seizures and other symptoms of toxicity and withdrawal (e.g., unmasked spasticity of withdrawal) [63, 97, 114, 115, 119, 126]. Paralytic agents may be used to limit spasticity and convulsions, but there is a risk of status epilepticus going unrecognized clinically in a chemically paralyzed patient [119]. Electroencephalography monitoring is recommended if these patients are chemically paralyzed. Succinylcholine use should be limited; it should not be administered to patients who may have been comatose for prolonged periods, who have neuromuscular diseases, or who are suspected to be at risk of rhabdomyolysis or trauma. Patients with neuromuscular disease have altered muscle fiber receptors, resulting in hypersensitivity to hyperkalemia that may follow succinylcholine administration. Cardiac arrest may occur in these patients after the administration of succinylcholine [130, 131] [Level III].

Common Errors in Baclofen Poisoning

Failure to appreciate airway compromise

Failure to recognize the danger of succinylcholine administration in patients with neuromuscular disease

Failure to use short-acting agents when treating hypertension or hypotension and tachycardia

Failure to recognize nonconvulsive (akinetic) status epilepticus

Failure to consider the potential for prolonged, profound CNS depression with overdose

Failure to differentiate between toxicity, withdrawal, and infection

Failure to resume baclofen treatment after acute or chronic toxicity resolves, precipitating withdrawal

Withdrawal from intrathecal baclofen may be resistant to various treatments and may require reinstitution of intrathecal baclofen [68, 117, 126]. Case reports suggest that dantrolene may be helpful in treating baclofen withdrawal, but this is not well established [132]. It seems more sensible to resume baclofen promptly rather than initiate dantrolene therapy [115, 119]. Cyproheptadine has also been used in the treatment of baclofen withdrawal in both children and adults given its resemblance to serotonin syndrome in some cases [123, 133] [Level III].

Infectious

Pump infections may be treated by removal of the pump and intravenous antibiotic administration. Alternatively, antibiotics may be administered via the pump [77, 85] [Level III].

Specific Antidotal Treatments

In prior case reports of baclofen overdose, physostigmine has been administered as an antidote [96, 125, 134, 135]. Additionally, flumazenil has been

given alone [65, 92, 103, 136, 137] or with physostigmine [56] in similar reports of baclofen poisoning. However, at this point, there is no clear evidence that either agent is advantageous, and further study would be warranted to support specific indications for use in baclofen poisoning. Ondansetron also has been reported as an antidote in a case report, but this agent has not been studied further [91]. In a single study, intravenous lipid infusion was trialed in dogs for treatment of baclofen poisoning and seemed to have a favorable outcome [138] [Level III].

Criteria for ICU Discharge in Baclofen Poisoning

Resolution of altered mental status and seizures

Resolution of blood pressure, pulse, and temperature abnormalities

Resumption of baclofen initiated without evidence of withdrawal

Special Populations**Pediatric Patients**

Respiratory arrest occurred in a 22-month-old infant who ingested 10.9 mg/kg of baclofen [27]. Six children, age 2–6 years, presented after oral baclofen overdose; two children required intubation, and one child experienced seizures. Signs and symptoms were similar to those reported in adults [129]. An 8-year-old child presented with diminished responsiveness and vomiting then hypothermia, bradycardia, flaccidity, and areflexia after an intrathecal baclofen overdose [99]. In a case series of adolescents ingesting baclofen, 9 of 14 required intubation; their symptoms were similar to the symptoms seen in adults [65]. Another case involving an adolescent describes exam findings of coma and bradycardia in addition to seizures after abusive oral baclofen use [64]. Baclofen withdrawal syndrome also presents similarly in children and adults [57].

Pregnant Patients

Pregnant women and nursing mothers generally are excluded from baclofen treatment [5]. However, cases of intrathecal baclofen administration during pregnancy have been reported in the literature [139–141]. If a pregnant woman presents with baclofen toxicity, she should be treated supportively, as recommended for nonpregnant patients.

Elderly Patients

Peak plasma concentrations occur later after ingestion in elderly patients [43]. This delay may prolong the clinical course in elderly patients.

Other Patients

Patients with impaired renal function are at risk for developing toxic symptoms soon after initiating even low-dose baclofen. Patients on stable regimens of baclofen may develop toxicity if creatinine clearance declines [49, 94, 127, 142]. Serum creatinine levels may remain normal, despite diminished creatinine clearance [49].

Key Points in Baclofen Poisoning

1. Patients who receive aggressive supportive care generally survive baclofen toxicity.
2. There is no clinically available antidote that reliably reverses baclofen toxicity.
3. Seizures, resulting from either toxicity or withdrawal, generally respond to benzodiazepines.
4. Differentiating between baclofen toxicity and withdrawal can be difficult.
5. Generally, hypothermia suggests toxicity, whereas hyperthermia suggests withdrawal or possibly infection.
6. Baclofen toxicity can mimic brain death clinically.
7. Prompt resumption of baclofen administration is often essential for the prevention and treatment of baclofen withdrawal.

The centrally acting muscle relaxants are a group of drugs that act in the central nervous system (CNS) to mitigate tension and spasm of skeletal muscles. Drugs within this group are structurally heterogeneous and act at a variety of receptors in the CNS. Muscle relaxants that act at the level of the spinal cord, such as baclofen, or peripherally, such as dantrolene, are discussed in their respective chapters.

Many of the centrally acting muscle relaxants have been available for decades. Carisoprodol, for example, was licensed in 1956 as a prescription, noncontrolled, centrally acting skeletal muscle relaxant. It is metabolized to the anxiolytic meprobamate [1, 2]. Others in the group may be compounded with analgesics: chlorzoxazone was first introduced in 1958 as the drug alone or in combination with salicylates or acetaminophen [3, 4]. Methocarbamol was reported in 1960 to effectively relieve muscle spasm in a patient with black widow spider poisoning [5] and in a case series of 100 patients with a variety of acute and chronic orthopedic conditions [6]. Metaxalone was patented in 1962 [7]. Diazepam, introduced in 1963, was the second benzodiazepine to be approved in the United States for humans, and has been used as an anxiolytic and anticonvulsant, as well as a centrally acting muscle relaxant [8, 9]. A 1964 double-blind investigation of 200 patients with low back pain and discomfort concluded that metaxalone diminished acute reflex skeletal muscle spasm [10]. Although a 1972 double-blind crossover trial of the tricyclic amine cyclobenzaprine demonstrated minimal improvement in patients with cerebral or spinal spasticity [11], a 1975 study of several animal models suggested that the drug could be used to mitigate excessive tonic skeletal muscle activity in humans [12]. Cyclobenzaprine has been available as a centrally acting muscle relaxant since 1977 [9].

Meprobamate and diazepam may be habit forming. The United States, for example, officially lists them as controlled substances [7]. Effective January 11, 2012, carisoprodol became a schedule IV controlled substance at the US federal level. Carisoprodol has been abused for its sedative and relaxant effects and to augment

the effects of other drugs [13]. In overdose, the centrally acting muscle relaxants are relatively safe when not combined with other agents. For example, a 1-year retrospective review of pure skeletal muscle relaxant exposure, including the centrally acting agents carisoprodol, chlorzoxazone, and cyclobenzaprine, revealed that morbidity and mortality were low [14].

Much of the clinical experience with muscle relaxants is limited to case reports and case series. Data reported in this chapter should therefore be interpreted cautiously.

Biochemistry and Pharmacology

The chemical structures of the agents discussed in this chapter are shown in Fig. 1. Their pharmacokinetics and metabolism are summarized in the accompanying box.

Pharmacokinetics of Centrally Acting Muscle Relaxants

Carisoprodol

Volume of distribution: unknown

Protein binding: 58%

Mechanisms of clearance: hepatic to hydroxycarisoprodol, hydroxymeprobamate, and meprobamate

Active metabolites: meprobamate (4.7% of dose)

Chlorzoxazone

Volume of distribution: unknown

Protein binding: unknown

Mechanisms of clearance: unknown

Active metabolites: none

Cyclobenzaprine

Volume of distribution: unknown

Protein binding: 93%

Mechanisms of clearance: hepatic to norcyclobenzaprine; may undergo enterohepatic cycling; 50% renally as inactive metabolites; via bile in feces as unchanged drug

Active metabolites: none

(continued)

Diazepam

Volume of distribution: 0.7–2.6 L/kg

Protein binding: 96–97%

Mechanisms of clearance: 4'-hydroxylation and conjugation; N-demethylation to nordiazepam

Active metabolites: nordiazepam

Meprobamate

Volume of distribution: 0.75 L/kg

Protein binding: 20%

Mechanisms of clearance: rapid hepatic; 8–20% in urine as unchanged drug; 10% as metabolites in feces

Active metabolites: none

Metaxalone

Volume of distribution: unknown

Protein binding: unknown

Mechanisms of clearance: unknown

Active metabolites: none

Methocarbamol

Volume of distribution: unknown

Protein binding: unknown

Mechanisms of clearance: O-demethylation and hydroxylation; conjugation; 99% excreted in 72-h urine

Active metabolites: guaifenesin

Orphenadrine

Volume of distribution: 4.3–7.8 L/kg

Protein binding: 20%

Mechanisms of clearance: extensive hepatic; demethylation; up to 30% may be eliminated unchanged in acidic urine; 60% excreted in 72-h urine

Active metabolites: nororphenadrine

Data from references [7, 9, 15, 16]

Chlorzoxazone

Chlorzoxazone is 5-chloro-2-benzoxazolinone and is derived from the more toxic zoxazolamine [3].

Cyclobenzaprine

Cyclobenzaprine HCl is a tricyclic amine salt, 3-(5H-dibenzo [a,d]cyclohepten-5-ylidene)-N,N-dimethyl-1-propanamine hydrochloride. It is structurally related to the tricyclic antidepressants; only a double bond on the central ring distinguishes it from amitriptyline [9, 17]. Cyclobenzaprine, which may undergo enterohepatic cycling, is metabolized in the liver to norcyclobenzaprine.

Diazepam

Diazepam is a benzodiazepine that undergoes 4'-hydroxylation and conjugation as well as N-demethylation to the active metabolite nordiazepam; other metabolites are the active but nonaccumulating 3-hydroxy derivatives temazepam and oxazepam [9]. The metabolism of diazepam is described in greater detail in ► Chap. 45, "Anxiolytics, Sedatives, and Hypnotics."

Methocarbamol

Like carisoprodol and meprobamate, methocarbamol is a member of the carbamate class. Its formula is 3-(*o*-methoxyphenoxy)-2-hydroxypropyl-1-carbamate [6]. The phenyl ring undergoes O-demethylation and hydroxylation; conjugation of the parent drug and metabolites follows. Guaifenesin, an expectorant, is an active metabolite [9].

Metaxalone

Metaxalone is 5-(3,5-dimethylphenoxy)-2-oxazolidinone [7].

Carisoprodol and Meprobamate

Carisoprodol is *N*-isopropyl-2-methyl-2-propyl-1,3-propanediol dicarbamate or isopropyl meprobamate [7]. It is hepatically metabolized to hydroxycarisoprodol, hydroxymeprobamate, and the active form meprobamate. Meprobamate is 2-methyl-2-propyl-1,3-propanediol dicarbamate [7].

Fig. 1 Chemical structures of centrally acting muscle relaxants

Orphenadrine

Orphenadrine (*o*-methyldiphenhydramine) is classified as a skeletal muscle relaxant, anticholinergic, and

antihistaminic agent [7]. As a substrate for the cytochrome P-450 isoenzyme (CYP3)A4 and an inhibitor of CYP2D6, orphenadrine may have a number of unpredictable pharmacologic interactions [15].

Pathophysiology of Therapeutic and Toxic Effects

Carisoprodol and Meprobamate

Carisoprodol is active in the descending reticular formation and spinal cord, where it inhibits interneuronal transmission. Both carisoprodol and its active metabolite meprobamate are indirect γ -aminobutyric acid (GABA)_A receptor agonists that open the neuronal chloride channel and induce hyperpolarization. This mechanism is similar to that of the benzodiazepines (see Fig. 3 of ► Chap. 45, “Anxiolytics, Sedatives, and Hypnotics”) [1].

Chlorzoxazone

Chlorzoxazone inhibits polysynaptic reflex pathways that produce and maintain muscle tone in the subcortex and spinal cord, and it appears to relieve musculoskeletal spasm more effectively than neurogenic spasm [3, 4].

Cyclobenzaprine and Orphenadrine

Cyclobenzaprine relieves skeletal muscle spasm of local origin but does not exert its action directly on the skeletal muscle, at the neuromuscular junction, or at the level of the spinal cord. Rather, it acts on the brainstem to reduce tonic somatic motor activity [17]. In overdose, its toxicity is related to its antagonism of muscarinic acetylcholine receptors and the resultant anticholinergic syndrome. A similar toxic profile is seen with the diphenhydramine analogue orphenadrine [9]. However, orphenadrine is a more potent fast voltage-gated sodium channel antagonist than cyclobenzaprine, a property that may be important in the clinical manifestations of overdose.

Diazepam

The benzodiazepine diazepam has multiple therapeutic uses, one of which is skeletal

muscle relaxation. It increases the action of the inhibitory neurotransmitter GABA in the limbic and reticular systems and in the CNS in general (see Fig. 3 in ► Chap. 45, “Anxiolytics, Sedatives, and Hypnotics”) [8, 16]. The pathophysiology of benzodiazepine effects is described in detail in ► Chap. 45, “Anxiolytics, Sedatives, and Hypnotics.”

Metaxalone

Metaxalone has an unknown mechanism of action, although no direct effects on the striated muscle, the motor end plate, or the nerve fiber are reported [18]. As may largely be the case for several of the other agents discussed in this chapter, the drug’s sedative properties are most likely to explain its therapeutic effects [10].

Methocarbamol

This drug, which is believed to act primarily at the interneurons of the spinal cord, blocks multisynaptic reflexes [6].

Clinical Presentation and Life-Threatening Complications

The ingestion of pure centrally acting muscle relaxants is generally associated with low morbidity and mortality. The clinical manifestation of overdose is predominantly CNS depression. The available data on the clinical toxicology of these agents are relatively sparse, but several investigators have described their experience with certain members of this class. Logan and colleagues [19] compiled a series of 104 incidents of impaired driving in which the drugs carisoprodol and/or its metabolite meprobamate (used alone as an anxiolytic) were detected in the blood of drivers. Reports of erratic driving and symptoms consistent with CNS depression were common but may have been attributable to coingestion of ethanol. In 21 cases, however, such behavior was witnessed in the absence of drugs other than

carisoprodol or meprobamate. A retrospective review of carisoprodol-related deaths in Jefferson County, Alabama, over a nearly 12-year period found that the skeletal muscle relaxant was present in 24 cases. Although the mechanism of death in 82% of these cases was respiratory depression, consistent with the action of carisoprodol or its metabolite meprobamate, carisoprodol was never the only one detected at autopsy and was never determined to be the sole cause of death. Of note, propoxyphene, a cardiac and neuronal sodium channel blocking agent, was present in a third of the cases [20]. Carisoprodol has been reported in three cases of illicit use in which it was combined with the nonopioid, nonsteroidal tramadol [21]. Carisoprodol has also been implicated in a case report of myoclonic encephalopathy. After the ingestion of 35 g of carisoprodol, agitation, tachycardia, and myoclonus developed in a 39-year-old man. His plasma carisoprodol concentration was 71 mg/L, and the meprobamate concentration was 118 $\mu\text{mol/L}$ [22].

In cases of cyclobenzaprine or orphenadrine overdose, an anticholinergic syndrome may be the predominant clinical manifestation (see ► Chap. 23, “Anticholinergic Syndrome”). In a 5-year review of cyclobenzaprine exposure [23], toxicity appeared to be related primarily to anticholinergic effects, even if overdoses did not produce the neurologic and cardiovascular toxicity of the structurally related tricyclic antidepressants. Neurologic and cardiovascular complications may follow an overdose of orphenadrine. In a case report, a 3-year-old boy ingested an unknown quantity of orphenadrine and presented with tonic-clonic seizures and ventricular tachycardia [24]. A 2-year-old girl who ingested 400 mg also presented with seizures and an episode of ventricular tachycardia; her initial plasma orphenadrine concentration was 3.55 mg/L [25].

In a case series of severe meprobamate poisoning, coma, hypotension, and hypothermia complicated the clinical course in four patients, and one required resuscitation after cardiac arrest. Peak plasma concentrations ranged from 800 to 923 $\mu\text{mol/L}$ (176–203 mg/L) (therapeutic, 28–55 $\mu\text{mol/L}$ [6–12 mg/L]). Three were treated with charcoal hemoperfusion. All four survived

without sequelae [26]. Although the exact mechanism of meprobamate’s cardiac toxicity is not established, one study observed that none of the seventy-four patients with signs of meprobamate toxicity, including cardiac failure, had prolongation of their QRS on EKGs [27]. Of note, authors Buire et al. point out that patients who are tolerant to meprobamate may have higher plasma concentrations of the drug with relatively normal levels of consciousness, as assessed by their Glasgow Coma Scale [28].

Dependence and Withdrawal

Patients who are prescribed carisoprodol are at risk to become dependent on its metabolite meprobamate. In an uncontrolled Norwegian study of prisoners who had been taking carisoprodol for a minimum of 9 months, abstinence symptoms, including anxiety, insomnia, irritability, headache, and muscular pain, were observed when the drug was withdrawn over a 2-week period. No seizures or psychoses were noted [29]. Reeves et al. reported a case in which a patient abruptly discontinued the use of carisoprodol and presented with a variety of effects including visual hallucinations, bizarre behavior, and anxiety [30].

Diagnosis

The diagnosis of skeletal muscle relaxant overdose depends primarily on the history and physical examination.

Some hospital laboratories may be able to detect or even measure concentrations, for example, of carisoprodol or meprobamate, but it is more likely, particularly in smaller hospitals, that outside reference laboratories must be contacted to arrange these assays. Furthermore, the screening immunoassays commonly used by hospital clinical laboratories may indicate false-positive results for tricyclic antidepressants if cyclobenzaprine is present. Cyclobenzaprine and its metabolite norcyclobenzaprine are among a number of

polycyclic compounds that may cross-react with tricyclic antidepressants on immunoassay or high-performance liquid chromatography of blood, and cyclobenzaprine may have the same effect on a colloidal metal immunoassay of urine [17, 31]. The cholinergic agent physostigmine may serve as a diagnostic tool in cases of cyclobenzaprine or orphenadrine overdose. There are rare reports of seizures and asystole associated with physostigmine administration, usually in polypharmacy overdoses, and conclusions about a cause-and-effect relationship are questionable [16]. When appropriately administered it is a relatively safe drug. The clinical pharmacology of physostigmine is described in ► Chap. 161, “Physostigmine.”

Treatment

The cornerstone of treatment of toxicity with these agents is supportive care. Patients should be monitored on telemetry and may require ICU level of care based on their symptoms and signs.

Indications for ICU Admission in Poisoning by Centrally Acting Muscle Relaxants

Coma

Respiratory failure

Seizures, hypotension, and QRS prolongation, which may occur in cases of orphenadrine overdose

Hypotension, cardiovascular failure without QRS widening with meprobamate

Cardiogenic shock requiring catecholamine support or mechanical support such as extracorporeal membrane oxygenation

Gastrointestinal Decontamination

If a patient is seen shortly after ingestion, administration of activated charcoal may theoretically decrease drug absorption. However, there is no evidence that the administration of activated charcoal will affect either the clinical

course or outcome. Activated charcoal should be given cautiously, if at all, to patients who have ingested a drug that may cause a rapid decrease in level of consciousness and airway protection.

Extracorporeal Removal Techniques

Meprobamate has a small volume of distribution and limited protein binding; it is moderately dialyzable. In the case series of severe meprobamate poisoning noted earlier, charcoal hemoperfusion performed in three patients reduced the plasma half-life as much as threefold, from 8.3 to 2.6 h [26]. Data concerning the efficacy of other centrally acting muscle relaxants are limited, although extracorporeal removal techniques would not be expected to significantly hasten the removal of agents with large volumes of distribution and/or extensive protein binding.

Flumazenil

Carisoprodol and its active metabolite meprobamate act as indirect GABA_A agonists and, like the benzodiazepines, enhance GABA-mediated CNS neuronal chloride ion channel opening, thereby inducing hyperpolarization (see Fig. 3 in ► Chap. 45, *Anxiolytics, Sedatives, and Hypnotics*). Flumazenil was reported to reverse CNS depression in a woman who had a Glasgow Coma Scale score of 9 after carisoprodol ingestion. Her respirations were shallow at 18 breaths/min, and her pupils were reactive at 2 mm. She received two 2-mg naloxone doses without effect. Ten minutes later, she received flumazenil (0.2 mg intravenously over a period of 2 min), and within 2 min, she became more alert, with somewhat dysarthric speech. A second dose 5 min later normalized her mental status completely within 2 min [2]. Rarely reported in overdose, chlorzoxazone was cited in one case report of a patient who became comatose on two occasions after toxic ingestion of this skeletal muscle relaxant. Although the patient had only therapeutic to subtherapeutic benzodiazepine levels present,

flumazenil was used and appeared to at least transiently reverse the CNS depression of chlorzoxazone [4]. The presence of an unrecognized benzodiazepine may explain the observed effect of flumazenil. Based on the aforementioned case reports, however, routine use of flumazenil is not recommended in the management of overdose, particularly if the patient has been taking any of these agents chronically. A complete discussion of the clinical pharmacology of flumazenil may be found in ► [Chap. 148, “Flumazenil.”](#)

Physostigmine

Although case reports [24, 25] of orphenadrine overdose attribute the resolution of ventricular tachycardia to physostigmine, the empirical use of this potentially toxic cholinergic agent should not precede the institution of standardized protocols for dysrhythmias.

Prevention and Treatment of Carisoprodol or Meprobamate Withdrawal

There is no standard treatment regimen for patients with carisoprodol dependence and most patients are treated for the symptomatic complaints of withdrawal [13]. The authors of the Norwegian study noted earlier suggested that a gradual reduction in carisoprodol dosing may prevent withdrawal symptoms [29]. Similarly, if chronically administered carisoprodol or meprobamate is discontinued abruptly, prompt resumption of drug treatment may prevent withdrawal.

Criteria for ICU Discharge in Poisoning by Centrally Acting Muscle Relaxants

Patient awake with adequate airway protection
Patient otherwise hemodynamically stable
without electrocardiographic conduction disturbances

Key Points in Skeletal Muscle Relaxant Overdose

1. Consider skeletal muscle relaxant overdose in patients with anticholinergic signs such as hyperthermia, disorientation, hallucinations, delirium, seizures, sinus tachycardia, and mydriatic pupils.
2. Consider skeletal muscle relaxant overdose in patients with hypotension, bradycardia, depressed respirations, areflexia, hypotonia, myoclonic encephalopathy, or rapid onset of coma.
3. Most cases resolve with supportive care only.
4. Appropriate resumption of drug treatment may prevent carisoprodol/meprobamate withdrawal.

Overview

Acetaminophen (paracetamol) was first discovered in Germany in 1887. It was initially rejected in favor of the structurally related phenacetin, as it was considered too toxic. It was only when restudied in the late 1940s that it was recognized as safer than alternative agents [1]. It was first marketed as an antipyretic and analgesic in the USA, as Tylenol, and UK, as Panadol, in the 1950s [2].

Toxicity from acetaminophen overdose was initially recognized in 1966, about 10 years after marketing, when the first cases were reported in Scotland [3, 4]. At that time there were no effective therapies, and morbidity and mortality from acetaminophen overdose climbed steadily as overdoses increased (Fig. 1) [5]. In the 1970s there were a significant number of cases in the Royal Infirmary poisons unit in Edinburgh, and Laurie Prescott and colleagues did important work, allowing rapid progress in knowledge. Initial studies showed the relationship of plasma concentration of acetaminophen to risk of toxicity (II-3) [6]. Animal studies had suggested both the mechanism of action of acetaminophen and potential antidotes. Studies were then done in the UK and North America evaluating three of these, cysteamine, methionine, and acetylcysteine. By the end of that decade the evidence was clear from UK data that acetylcysteine (*N*-acetylcysteine, NAC) was the antidote of choice (II-3) [7], but for many years there were differences in the approach to giving this antidote, as intravenous formulations were at that time not licensed for use in the USA [8, 9]. Despite an available antidote, which halted the increase in mortality, deaths did not subsequently decline. As a result, in the UK, changes were introduced in 1998 to the pack sizes available for over-the-counter sale (maximum 16 g in a pharmacy, 8 g in a general store sale), in an attempt to reduce mortality [10]. The magnitude of change in mortality and morbidity this has caused remains a topic of debate [11].

Because acetaminophen is available without prescription, “over-the-counter,” worldwide it is commonly used in overdose, but the precise number of deaths caused is uncertain. In the UK, for example, at least 150 deaths per annum may be attributed to ingestion of acetaminophen with and

without ethanol, and an almost equal number of deaths involve ingestion of acetaminophen as part of an overdose [5]. Acetaminophen remains the most common cause of acute liver failure as seen in hospitals in the USA and UK, and is important in many other countries [12, 13]. Among overdose patients, there are a number of patients who suffer from toxicity due to taking supratherapeutic doses. This is in part due to the confusion in labeling of acetaminophen-containing medications, the availability of different types of products containing acetaminophen, a lack of understanding in the community of what products contain acetaminophen [14], and the narrow therapeutic index of this compound. It may also be that factors such as acute starvation are as important in man as they are in animal models of acetaminophen toxicity. Repeat ingestion of supratherapeutic doses appears to result in a greater risk of liver damage than the same dose as a single ingestion [15].

Although antidote therapy is effective if given soon after ingestion of an overdose, it is clear that its efficacy declines over time and in patients who take multiple therapeutic doses in excess it is often too late for acetylcysteine to be effective (II-2) [16]. Although other approaches to therapy have been studied in animal models these are yet to be put into the clinic. In patients with severe liver injury liver transplantation may be effective. Present issues in clinical toxicology of acetaminophen include the use of safer, potentially shorter and simpler antidote regimens, better predictive tests for indicating which patients are at risk, and which therefore allow better risk stratification than the present nomograms that have been in use for 40 years.

The introduction of modified release preparations of acetaminophen has resulted in a problem in overdose management, since these make risk assessment more difficult, as the nomograms may not be applicable due to delays in acetaminophen absorption [17]. In addition over the past few years intravenous acetaminophen has become more widely used, particularly postoperatively, and sadly cases of toxicity have been associated with supratherapeutic use by this route [18].

Fig. 1 Deaths from acetaminophen poisoning in England 1969–2011, (a) total numbers; (b) per million population. Down arrows indicate potential influences on mortality: introduction of acetylcysteine as an antidote in 1975; reduction in pack sizes available for sale over-the counter

in 1998; and withdrawal of propoxyphene containing acetaminophen codrug (coproxamol) over 2 years 2005–2007 (Data from Bateman 2014 Clin Tox 52 821–23, with kind permission of Prof R J Flanagan)

Clinical Pharmacology

Although acetaminophen has been used extensively for more than 50 years, its precise mechanism of action therapeutically remains unclear. While it has been shown to inhibit both cyclooxygenase 1 (COX-1) and cyclooxygenase

2 (COX-2) enzymes with a reduction in prostaglandin (PG) production [19, 20], its pharmacological effect appears to be primarily mediated via inhibition of COX-2 and prostaglandin E2 synthesis (PGE2) [21, 22]. In vivo, acetaminophen has similar effects to selective COX-2 inhibitors, with only mild COX-1 effects [23]. Animal

studies have suggested that acetaminophen inhibits COX-3, a variant of COX-1 [23, 24]. COX-3 encodes proteins with different amino acid sequences to COX-1 and COX-2, and so it is unlikely that it plays a significant role in PG-mediated pain and fever. Furthermore, the low level of expression of COX-3 in humans suggests that it may be of little clinical relevance [25].

Despite similarities with classic nonsteroidal anti-inflammatory drugs (NSAIDs), however, the anti-inflammatory effect of acetaminophen is weak [24]. This may be related to peroxide concentration, as acetaminophen-induced COX inhibition is less active at sites of inflammation where peroxide concentration is high, but more active centrally at sites of low peroxide concentration, probably in the brain [19, 26]. Animal models suggest additional analgesic effects may be mediated via serotonergic [27], opioid [28], or cannabinoid systems [29]. Animal studies using COX-2 knockout mice have also demonstrated that COX-2 is responsible for the febrile response [30], suggesting that the antipyretic mechanism of acetaminophen may be mediated via COX-2 inhibition. In overdose none of these pharmacological effects are likely to be important in the majority of patients, although increased kaliuresis with resultant hypokalaemia suggests an effect on renal function associated with the effects of acetaminophen on renal prostaglandins [31].

The kinetics and metabolism of acetaminophen at therapeutic doses are well understood. Gastric emptying is the rate-limiting step in absorption, and, as acetaminophen is absorbed rapidly from the small intestine, speed of absorption of acetaminophen has been used as a measure of gastric motility. Absorption is usually complete by 60–90 min after a therapeutic dose. Liquid preparations may be completely absorbed within 20 min [32]. With ingestion of excessive doses of standard-release preparations, absorption may be delayed but is almost invariably complete within 4 h. Coingested drugs that delay gastric emptying may delay absorption of acetaminophen. Thus a peak serum acetaminophen concentration occurring later than 4 h after overdose is

rare but has been noted, for example, after coingestion of drugs that impair gastric motility, such as the opioid propoxyphene [33] and anticholinergic diphenhydramine [34]. A major concern for clinical toxicologists has been the introduction by pharmaceutical companies of modified release acetaminophen preparations. As these are associated with peak plasma concentrations delayed more than 4 h after overdose they interfere with the use of the standard nomogram approach to assessing acetaminophen dose, and hence risk of toxicity [35–37].

In therapeutic dose acetaminophen elimination follows first-order kinetics. It has a half-life of 2–4 h, which is prolonged in patients with acute acetaminophen-induced liver damage. At therapeutic doses protein binding is 15–20%, and the volume of distribution is approximately 0.9 L/kg [32]. It is obviously more difficult to study these aspects in patients with overdose, as the dose actually absorbed is often uncertain. With the onset of liver injury the elimination of acetaminophen is delayed [6, 38]. More than 90% of acetaminophen is conjugated in the liver by a combination of sulfation and glucuronidation; approximately 4–7% is excreted unchanged in urine. The remainder (about 4% at therapeutic doses) is metabolized by the cytochrome P-450 mixed-function oxidase system [39], primarily by CYP2E1 with a smaller contribution by CYP1A2, to a toxic metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI).

Pharmacokinetics of Acetaminophen at Therapeutic Dose

Volume of distribution: 0.9 L/kg

Protein binding: 15–20%

Mechanisms of clearance (at therapeutic dose): hepatic >90%, renal 4–7%

Toxic metabolite: *N*-acetyl-*p*-benzoquinoneimine

Methods to enhance clearance: dialysis (may be appropriate to consider in massive overdose but is normally used in patients therapeutically for management of renal failure)

Pathophysiology

The basis of acetaminophen toxicity is its metabolic pathway and the availability of natural glutathione (Fig. 2). Acetaminophen is an example of a substance that undergoes hepatic metabolism to a toxic metabolite (other examples include carbon tetrachloride, methanol, and ethylene glycol). The metabolizing enzymes are distributed throughout the body, but the majority of these are found in the liver, with the highest concentration in the centrilobular region (zone 3), which is composed of hepatic acinar cells. A secondary area of increased concentration is in the kidneys. Neither acetaminophen nor its conjugated metabolites are harmful. However, the metabolite generated by CYP2E1 is potentially toxic [40–42]. This metabolite, *N*-acetyl-*p*-benzoquinoneimine (NAPQI), is very short lived. It binds to the hepatic cell membrane and injures the lipid bilayer, if not neutralized by an antioxidant [43], and glutathione is the primary antioxidant naturally present in the liver that conjugates and detoxifies this metabolite [39, 42, 44–47].

Mitochondrial injury is a component of hepatic injury, and agents that prevent mitochondrial injury reduce liver injury from acetaminophen in animals [48].

At therapeutic doses, acetaminophen is an extraordinarily safe drug with minimal adverse effects. However, in an animal model of acetaminophen overdose, NAPQI begins to bind to hepatocytes and causes arylation, cellular injury, and possibly death when hepatic glutathione stores have been depleted to less than 70% of normal values [44].

Similar reactions are believed to occur in man. Serious liver damage after a single 75 mg/kg body weight dose of acetaminophen is rare, even in patients at increased risk. In patients without risk factors, a dose less than 150 mg/kg body weight is unlikely to cause serious liver damage [16]. Children younger than 6 years appear to be more resistant to acetaminophen toxicity than adolescents and adults on a weight basis. This may be because the liver is a proportionally larger organ in children than adults. Several large studies of young children have demonstrated that in this

Fig. 2 Metabolism of acetaminophen showing main metabolites, mechanism of toxicity, and primary site of action of acetylcysteine (“?? NAC” indicates unknown mechanism of benefit in liver failure prophylaxis, see text)

age-group, a single ingestion of 200 mg/kg or less is highly unlikely to result in significant toxicity (II-3) [49–52].

Chronic supratherapeutic dosing of acetaminophen may also result in toxicity. The manufacturers' recommended daily amount is 4 g/day or less for adults and 75 mg/kg/day or less for children. Toxicity has been reported with ingestion of more than these recommended doses for a day or longer [53–55]. Retrospective case series in children have reported therapeutic doses (20–25 mg/kg/day) being associated with hepatotoxicity [56, 57], but the accuracy of these dose estimates is uncertain.

Whether chronic acetaminophen dosing at normal therapeutic doses causes liver damage is a subject which has been raised by studies suggesting small increases in ALT with chronic dosing in normal populations [58]. The clinical relevance of a small increase in ALT is likely very low, and others have suggested little evidence of any toxicity from such dosing [59].

Modulators of Toxicity

Toxicity results when the amount of NAPQI produced from acetaminophen metabolism overwhelms the capacity for glutathione-mediated detoxification. Theoretically, any compound that induces CYP2E1 could increase the amount of NAPQI produced and thus increase the likelihood of toxicity. Inducers of CYP2E1 include ethanol, rifampicin, isoniazid, and carbamazepine (II-3) [60]. Clinical series suggest that patients who chronically ingest drugs that induce CYP2E1, or smoke tobacco, may have poorer outcomes than the general population after acetaminophen overdose (II-3) [61–64]. In addition coingestion of opiates seems to be associated with increased toxic effect in acetaminophen overdose [65]. Patients with depleted glutathione stores from malnutrition, such as chronic alcoholics, may also be at increased risk (II-3) [15]. There is some evidence that coexisting conditions, in particular myopathies, may increase toxicity risk in overdose (II-3) [66]. Acute starvation also seems to increase risk of hepatotoxicity, as in patients

with acute dental pain. In contrast, concomitant ethanol and acetaminophen ingestion may decrease the effects of acetaminophen overdose because of inhibition and competition for CYP2E1 activity [67]. Phenytoin, which is not a CYP2E1 inducer, does not appear to increase the risk of acetaminophen-induced hepatotoxicity and, in fact, may offer hepatoprotection by increasing glucuronidation [68].

Age is also a modulator of toxicity. Young children appear to be more resistant to the toxic effects of acute acetaminophen overdose. Additionally, the incidence of hepatotoxicity is much lower than that observed in the general population [69]. The corollary to this is the increased risk of hepatotoxicity in the elderly (II-3) [15, 70, 71].

Clinical Presentation and Life-Threatening Complications

The clinical manifestations of acetaminophen toxicity can vary significantly, depending on the dose, time of presentation, and whether the toxicity results from acute or chronic ingestion. Patients who undergo medical evaluation within several hours after an acute ingestion may be asymptomatic or have only minor symptoms. Nausea, vomiting, and occasionally lethargy may occur early (typically within several hours of ingestion) in moderate to severe acetaminophen poisoning. In our experience, these symptoms usually decrease within 12–18 h and may possibly reflect direct effects of the parent compound (because resolution occurs with declining acetaminophen levels). Metabolic acidosis is a feature of evolving liver failure, but it and even coma have been reported within 4–6 h of a massive overdose, although coma is extremely rare, and should alert the physician to alternative diagnoses or coingestions such as opioids or benzodiazepines [72–74]. It is important to exclude hypoglycemia caused by acetaminophen-induced liver injury. Patients who first come to medical attention after the onset of signs of liver injury – generally at least 24 h after acute ingestion – may initially present with abdominal pain, encephalopathy, coagulopathy, and renal failure.

Hepatocytes are the primary target after an acetaminophen overdose. Given NAPQI's ultra-short half-life, its initial toxicity is limited to cells that synthesise it. Most of the life-threatening complications of acetaminophen poisoning are a direct result of acute liver injury and the systemic complications of liver failure. The role of inflammatory response is also important in the pathogenesis of liver damage, as inhibition of this process in laboratory animals results in less toxicity [75]. The clinical course most commonly observed with acute acetaminophen hepatotoxicity is hyperacute liver failure, which has been defined as the development of encephalopathy within 7 days of the onset of jaundice (although rarely in very severe acetaminophen poisoning cases death may occur before jaundice is apparent) [76–78]. Liver failure is the result of NAPQI-induced hepatocellular injury. The early histopathologic finding after acetaminophen overdose is centrilobular hepatic necrosis (zone 3) with periportal sparing [79, 80]. The centrilobular region is chiefly composed of zone 3 hepatic acinar cells, the site of highest metabolic activity. Hepatic necrosis results in the release of a wide range of substances into serum and severe metabolic derangements (e.g., acidosis, hypoglycemia, and hyperammonemia) from the loss of functioning liver.

It is also now clear that there is a consequent molecular signaling and response with necrosis, apoptosis, and an inflammatory response caused by an influx of inflammatory cytokines [81, 82]. In animal models drugs that affect this inflammatory response reduce hepatotoxicity. Coagulopathy and renal failure usually accompany liver failure, although the extent of different organ involvement may vary. Sepsis (both bacterial and fungal), cardiovascular collapse, and terminal ventricular dysrhythmias may also develop in patients with ALF. The injured liver has an ability to regenerate, and ALF is thus potentially reversible if the patient can be supported through the acute phase of poisoning, particularly in the case of acetaminophen poisoning, because hepatic regeneration occurs from cells situated in the periportal regions (zone 1), which tend to be

Table 1 Clinical characteristics of encephalopathy

Grade I	Slowed thought processes, slurred speech, untidy appearance, slight tremor
Grade II	Increased drowsiness, inappropriate behavior, easily elicited tremor
Grade III	Hypersomnolent, incoherent speech, marked confusion
Grade IV	Coma, no response to painful stimuli

unaffected by all but the most massive of acetaminophen overdoses.

Hepatic encephalopathy is the hallmark of ALF and develops in severe cases of acetaminophen-induced hepatotoxicity. In a series of 171 patients, grade II (Table 1) encephalopathy was noted at a median of 72 (range 38–120) h after an acute acetaminophen overdose. Grade IV encephalopathy was noted within 89 (range 51–141) h following an overdose occurring 12 (range 3–96) h after grade II encephalopathy [83]. Patients with grade III encephalopathy are at significant risk for cerebral edema. Death is most likely to occur 72–96 h after an overdose, although it may be delayed for up to 10–14 days. Death occurs most frequently as a complication of cerebral edema or sepsis. Patients who survive do not have permanent liver damage.

Renal failure in the setting of acetaminophen poisoning may be due to a direct renal effect of NAPQI, prerenally mediated acute tubular necrosis, and/or hepatorenal syndrome. Because CYP2E1 is present in renal tubules, NAPQI is generated in the kidney. Renal injury manifested by hematuria, proteinuria, and modest elevations in blood urea nitrogen and creatinine have been reported in as many as 8.9% of patients [84]. It typically develops within the first 24–48 h but is easily missed as the process takes a few days to peak. The injury is normally transient but may progress to anuric renal failure and require dialysis [84, 85]. Oliguric renal failure necessitating dialysis has been reported to occur in 1% of patients [86]. Renal failure associated with liver failure is typically delayed 48–72 and is a feature of severe outcome (II–3) [15, 85]. Clinically

significant nephrotoxicity in the absence of hepatotoxicity has been reported but is rare [87–89].

Other clinical manifestations associated with acetaminophen toxicity include pancreatitis and cardiotoxicity. Pancreatic inflammation, defined as serum lipase three times the upper limit of the normal laboratory value, may be found in 30% or more of patients with acetaminophen hepatotoxicity [90]. However, clinical pancreatitis is rare [85]. Cardiotoxicity, manifested by nonspecific electrocardiographic changes and alterations consistent with pericarditis, is also rare [85, 91]. The mechanisms responsible for these less common findings are unclear but in some cases may have been due to other undetected coingestants, such as propoxyphene causing cardiac effects [92].

Chronic Acetaminophen Overdose

The manufacturers' recommended maximum daily doses of acetaminophen are 4 g of acetaminophen in adults and 75 mg/kg in children. Ingestion of larger supratherapeutic quantities may result in hepatotoxicity. This is most common in the context of acute pain syndromes, as in dental pain, where toxic risk may be increased by acute starvation. In young children, although hepatotoxicity has been reported after as little as 150 mg/kg/day, the general experience is that due to a proportionally increased hepatic mass in children toxicity is less likely than in adults [56, 93, 94]. Medication error is an important potential risk in children [95], but Munchausen's-by-proxy must also be considered.

Chronic acetaminophen excess is usually a therapeutic misadventure. Common scenarios include those involving patients who increase their daily intake because they believe that it is safe, patients who use combination products such as acetaminophen and codeine along with acetaminophen, or caretakers who substitute adult for pediatric suppositories in a young child. The incidence of hepatotoxicity after chronic excess has not been extensively studied. Certain populations may be at risk, including patients who are fasting or who have ingested alcohol in the preceding 5 days [55]. Numerous cases of hepatotoxicity

have been reported in alcoholics after chronic acetaminophen excess, although the apparent frequency may be due in part to ascertainment bias [54]. A randomized, double-blind, placebo-controlled trial of 201 long-term alcoholic patients, failed to show liver injury by conventional blood tests when recommended doses of acetaminophen were not exceeded [96].

The clinical presentation of chronic acetaminophen toxicity is variable. Many patients initially come to medical attention during routine medication review and are taking excess for reasons such as acute or chronic pain disorders. These patients generally have no symptoms directly related to excessive acetaminophen use. Rarely cases may present as altered mental status from incipient ALF, but these usually seem to have had an acute recent increase in dose. This raises a possibility of adaption to regular excess acetaminophen dose, and most experienced clinicians will have come across patients who routinely take additional acetaminophen above recommended limits without apparent harm.

Diagnosis

Patients normally present in one of three scenarios:

- (i) With a history of a single overdose as part of an act of self-harm
- (ii) With a history of multiple ingestions as an act of self-harm
- (iii) As a result of therapeutic excess, as in the case of an acute pain syndrome treated with a cocktail of remedies, or confusion over the content and quantities of acetaminophen in different cold remedies

Occasionally therapeutic misadventure may occur in hospital environments, as with excess IV acetaminophen, or from regular excess oral dosing in underweight, nutritionally challenged patients.

Patients are often asymptomatic but with chronic therapeutic or repeat deliberate ingestion may present with right upper quadrant abdominal

tenderness, vomiting, or jaundice. *De novo* presentation with hepatic encephalopathy is extremely rare.

Laboratory Evaluation

Determination of risk in acetaminophen overdose is dependent on the time from the ingestion. Within the first few hours the acetaminophen blood concentration is currently the best predictor of outcome (II-2). A number of nomograms were produced in the 1970s based on a series of patients in Edinburgh who were not treated for their overdose. These lines start from the plasma concentration taken at least 4 h after ingestion in an attempt to avoid any misinterpretation due to measuring acetaminophen during the absorption phase. All have a half-life of 4 h, even though this is longer than that seen in normal therapeutic doses. The lines derive from graphs drawn by hand and eye that divide patients with and without hepatotoxicity as defined by a rise in ALT over 1000 IU/L. No deaths occurred in 54 patients in this series of 70 in those with a plasma concentration below a line commencing at 300 mg/L acetaminophen 4 h after ingestion, with the proportion of patients who developed an ALT over 1000 IU/L increasing from 23% at 100 mg/L to 60% at 200 mg/L [97]. Prescott used these data to develop a nomogram for the UK with a 4 h concentration of 200 mg/L (200 µg/mL; 1323 µmol/L) to determine treatment at a time when antidotes were being developed (II-3) [7]. Rumack and Matthew also published a similar nomogram that was reduced by the FDA to 150 mg/L for clinical use (150 µg/mL; 992 µmol/L) [8, 98]. Subsequently in the 1990s in the UK a risk assessment approach was adopted in patients with concentrations between lines drawn from 100 to 200 mg/L (662 and 1323 µmol/L) at 4 h (III) [99]. This assessment included determining whether patients were alcoholic, taking enzyme-inducing drugs, or were malnourished. Patients with these features were treated at the 100 mg/L nomogram line. In Australia a decision was made to move from the 200 mg/L nomogram to the 150 mg nomogram in 2008 [100].

In the UK in 2012 policy was changed by the UK regulator, the MHRA, in view of the death of a young woman who had not been thought to be high risk. All patients in the UK are currently treated using the 100 mg/L nomogram [101].

Whichever nomogram is being used it is important to have an accurately timed acetaminophen concentration and be aware of the units being used to report. Confusion can arise when different laboratories use mass and molar units; in the UK there has been standardization to mass units (mg/L) to avoid confusion, and potential failure to treat [102] (Fig. 3).

It is generally accepted that the accuracy of the nomogram for prediction becomes less reliable beyond 15 h, since the original dataset used had very few patients who presented late. Furthermore since the elimination of acetaminophen is reduced by liver injury [6] it would in theory be possible to use estimates of the half-life of the drug based on two or more times blood samples to establish whether injury to the liver had occurred. This is rarely used in practice but may be useful in managing individual patients, for example, those who wish to self-discharge against medical advice, or refuse antidote therapy.

A potential confounder is the accuracy of acetaminophen measurement at concentrations below 10 mg/L (66 µmol/L). Some laboratories have even higher cutoffs for reporting undetectable concentrations, and this may cause problems in interpretation of results in patients presenting late after their overdose. Some countries have also licensed modified release products of acetaminophen, and the nomograms are not likely to be accurate in this situation [17].

Other blood tests should be routinely measured at presentation, since these will be necessary to interpret progress in patients who are determined to require treatment with antidote. These include a measurement of renal function, normally creatinine, liver function tests, in particular transaminase activity, and prothrombin time, often measured as INR. Admission tests may be predictive of outcome [15, 103]. Other tests have been suggested to be abnormal in more severe poisoning, including urinary phosphate, urinary potassium, and plasma lipase. These have not been

Fig. 3 Acetaminophen treatment nomograms. Treatment is recommended if the plasma acetaminophen concentration is above the *solid* (150 mg/L at 4 h) line in North

America and Australia. In the UK and Ireland the *dotted-dashed line* (100 mg/L at 4 h) is used to determine therapy with acetylcysteine

adopted in routine practice. Some patients will have compensated or uncompensated metabolic acidosis shortly after ingesting a significant overdose [104]. This acidosis has been associated with increased lactate formation and has been postulated to occur as a consequence of impaired mitochondrial respiration at the level of ubiquinone by acetaminophen or NAPQI [105, 106]. This early-onset acidosis tends to resolve spontaneously within hours [104]. In patients whose clinical condition continues to deteriorate, however, acidosis often recurs and is highly predictive of lethality once ALF has developed.

ALT is a sensitive marker of liver injury, and traditionally an ALT of >1000 IU/L has been regarded as an index of “severe” hepatotoxicity in acetaminophen poisoning [107]. This definition was based on the requirement at that time to dilute samples with ALT above this activity to determine the result accurately. It is in reality poorly correlated with outcome, and ALT measurement is not part of the standard criteria now used to determine prognosis. However it remains a useful cutoff

point to use in clinical decisions regarding the severity of illness. Rate of rise of ALT is more important than its actual value, as rate of rise is better linked to extent of acute liver injury.

Prothrombin time (usually measured as INR) is one of the best readily available markers of functional hepatic damage, since unlike ALT, which provides information on cell injury, PT provides information about hepatic synthetic function. A rise in INR indicates a decrease in hepatic synthesis of vitamin K-dependent clotting factors (factors II, VII, IX, X). A rising PT in the setting of falling transaminase levels is an ominous finding. Serum transaminase concentrations will generally fall in both a patient who recovers from hepatic injury and one who develops ALF and massive hepatic necrosis. PT, however, will not usually improve if a patient has progressive liver injury, and it generally continues to rise in cases of ALF, especially in the absence of clotting factor replacement. The finding of a slightly elevated PT within hours after an acute overdose is common and usually the result of direct reversible

inhibition by acetaminophen of vitamin K–dependent clotting factor synthesis and not a marker of hepatic injury (II-2) [108].

In patients who have taken a single overdose and have acetaminophen concentrations below the nomogram limits, risk of serious hepatic damage is low; they can normally be discharged. Care should be taken, however, in patients who have recently consumed more than one ingestion (within a 24 h period) of acetaminophen, and in those coingesting drugs that may alter gastrointestinal motility and delay gastric emptying such as opioids or antihistamines [109]. It is wiser in these patients, and indeed a sensible precaution in all patients, to take account of the history of dose ingested, and where there is disparity between this and blood results clinicians should be cautious in their decision regarding early discharge, and double-check timings of ingestion and samples (III). Kinetic studies suggest a correlation between dose and concentration across a wide dose range [110], and historic case series indicate that history correlates with measured plasma acetaminophen concentration (II-3) [111, 112].

The product of acetaminophen and ALT has been suggested as a tool to better identify those patients at increased risk of serious liver injury [113]. Novel biomarkers are now being evaluated that appear to give earlier indications of liver injury than present laboratory tests; a lead candidate is the microRNA miR 122. Other biomarkers, of apoptosis and cell necrosis, may also have a future role (Fig. 4) [82].

Differential Diagnosis

Although acetaminophen is currently the primary cause of ALF, a number of other toxic and nontoxic etiologies must also be considered. Toxic causes include intrinsic, dose-related hepatotoxins such as carbon tetrachloride, chloroform, cyclopeptides from fungi (α -amanitin), copper sulfate, yellow phosphorus, and various herbal products. Botanicals that have been implicated as intrinsic hepatotoxins include pennyroyal oil from *Mentha pulegium*, chaparral, germander, Jin Bu Huan, and pyrrolizidine alkaloids from

Heliotropium, *Senecio* (tansy ragwort), *Crotalaria*, and *Symphytum* (comfrey) species. ALF may also result from idiosyncratic adverse drug reactions from, for example, phenytoin, valproic acid, isoniazid, halothane, or nonsteroidal anti-inflammatory agents. Idiosyncratic hepatotoxicity is not dose related and may occur after therapeutic dosing. Liver failure from methylenedioxymethamphetamine (MDMA) has also been described and may occur in association with severe MDMA-induced heatstroke, or be due to contaminants in the tablets [114]. Other causes of fulminant liver failure include viral hepatitis, sepsis, hypovolemic shock, cardiogenic shock, heatstroke, and Reye's syndrome [115]. Serology, clinical history, and occasionally histopathology help differentiate these entities.

The time course and the clinical and biochemical characteristics of shock liver may appear remarkably similar to acetaminophen-induced hepatic failure. Shock liver generally results from hemorrhage, hypovolemia, and the resultant hypotension secondary to trauma and operative procedures. Differentiating between shock and acetaminophen as the primary hepatic insult may prove challenging, especially in situations in which hypotension may have occurred and the patient has been taking therapeutic amounts of acetaminophen.

In light of the increasing number of reports of hepatotoxicity associated with chronic supratherapeutic dosing, acetaminophen should always be considered in cases that might otherwise be attributed to cryptogenic ALF. For any patient admitted to the critical care unit with ALF of unknown etiology, the earliest available blood specimen should be retrieved and tested for acetaminophen to assess whether it might be an etiologic factor. However, depending on the timing of the last acetaminophen dose, the plasma concentration may be low or nondetectable and cannot reliably exclude acetaminophen as the cause. Furthermore, in the setting of severe hyperbilirubinemia (≈ 25 mg/dL; 1.46 μ mol/L), some conventional acetaminophen assays performed by enzyme assay (GDS Diagnostics, Elkhart, IN) may cross-react with the bilirubin and result in a falsely elevated or false-positive acetaminophen

Fig. 4 Schematic diagram illustrating a range of novel markers that may have utility in prediction of hepatic toxicity and hepatic recovery in acetaminophen overdose. Measurement of biomarkers may identify acute liver injury early (miRNA-122, HMGB1, K18 isoforms) or provide prognosis of liver injury (Acetyl-HMGB1). In view of the multicellular and many aspects of acetaminophen-induced

liver injury, the use of this panel-based approach, alongside current markers, may enable patient stratification for the treatment and assessment of efficacy of novel therapeutic intervention strategies (*HMGB1* high-mobility group box-1) (Based on Dear and Antoine. 2014 Expert Rev. Clin. Pharmacol. Early online, 1–9)

determination. Measurement of plasma levels acetaminophen-protein adducts may be a useful adjunct tool to assess recent acetaminophen intake and may be of use in indicating that acetaminophen is a cause of acute liver failure of uncertain origin [116, 117].

Treatment

Acute Single Oral Ingestion

Decontamination with a single dose of activated charcoal should be performed if the patient is seen within 1 h of ingestion (II-2) [118]. It is unknown if activated charcoal alters the outcome in patients who have ingested excessive doses of acetaminophen. Caution should be exercised in patients who may have ingested other substances that might

reduce their conscious level while activated charcoal is being given, as there is a risk of aspiration in such patients. In the past, there was concern about activated charcoal and use of the oral antidote NAC, but the amount of acetylcysteine adsorbed was not considered clinically important.

Use of NAC is mandatory in all those patients above the nomogram line used in the country of treatment (II-2). This currently varies between “150 mg/L line” used in most countries and the “100 mg/L line” used in UK and Ireland. Use of this very conservative threshold in the UK has had major resource implications which have been questioned [119].

Acetaminophen intoxication by itself does not typically produce cardiorespiratory compromise unless the patient is in hepatic failure. Presence of such features should lead to a consideration of other causes, particularly coingested drugs. Rare

instances of patients presenting in coma and requiring endotracheal intubation shortly after an overdose have been reported [72]. This procedure should, however, not interrupt or delay the use of intravenous NAC. Acetaminophen is removed by dialysis, but this modality has little role in most overdoses given the efficacy of NAC as an antidote. In patients with renal failure haemodialysis will remove acetaminophen, and also NAC, with a doubling of the dose of NAC recommended [120].

Multiple Ingestions and Therapeutic Error

Assessing the need to treat patients in this scenario is more challenging, as there are no agreed criteria internationally. It is necessary to use a combination of history of dose ingested and blood tests taken on admission to determine treatment. As an example of the approach used in the UK, in patients who present less than 24 h after the last ingestion treatment with NAC is generally started if the history suggests an amount in 24 h greater than local guidelines. This dose may vary between 75 mg/kg in 24 h and as much as 200 mg/kg in 24 h in different countries. In patients who are not jaundiced, do not have right upper quadrant abdominal pain, and have had their last ingestion of acetaminophen more than 24 h previously it is reasonable to withhold NAC therapy until blood results are available, since the efficacy of the NAC falls with time. Treatment is then based on presence of acetaminophen in blood, or of evidence of liver injury using ALT and INR (prothrombin time). Decisions on stopping treatment will depend on the results of blood tests; if these suggest potential toxicity they should be repeated at the end of an appropriate time interval of NAC therapy, usually a full 21 h course of antidote.

Intravenous Acetaminophen Overdose

There is much less experience of use of NAC in IV acetaminophen overdose, but this has become more often as this route has become more widely used. The usual nomograms cannot be applied in

the situation of IV dosing, as the dose is given rapidly and the nomogram 4 h interval of assessment may not be correct. These patients may be subject to therapeutic errors, but also may be suffering acute starvation [18, 121]. There is uncertainty as to whether the much higher acetaminophen concentrations that result immediately following IV dosing have toxic significance as more toxic metabolites could be formed if conjugation pathways are overwhelmed. In addition many patients receiving IV acetaminophen have been fasted preoperatively, or are in intensive care units and not receiving full nutrition. Similar concerns may apply to those in intensive care with muscular dystrophies who are ventilated and receive acetaminophen (oral or IV) therapy for muscular dystrophies [66]. For these reasons some authors have suggested a lower dose threshold for intervention with NAC [18].

Acetylcysteine (*N*-acetylcysteine)

NAC is a highly effective antidote when administered soon after an acetaminophen overdose. It was selected from a range of potential glutathione donors in the 1970s. It acts as a glutathione substitute in addition to enhancing glutathione synthesis and increasing the amount of acetaminophen that undergoes sulfation (see Fig. 2) [45]. Its efficacy is primarily a function of time elapsed since the overdose. NAC is most effective when administered within the first 8 h after an acetaminophen overdose, and its effectiveness decreases incrementally every hour thereafter (II-2) [8, 97].

Indications for ICU Admission in Acetaminophen Poisoning

Significant acidosis

Any grade of encephalopathy

Coagulopathy requiring treatment

Significant renal failure

Different approaches to using NAC were developed in the UK and USA. In the 1970s an intravenous formulation of NAC was licensed in the UK for management of airways disease, and this was therefore used to administer the drug in

Table 2 Acetylcysteine regimens

Regimen	Loading dose	Followed by	Total dose
21 h IV	150 mg/kg over 1 h	50 mg/kg over 4 h	300 mg/kg
		100 mg/kg over 16 h	
72 h PO	140 mg/kg	70 mg/kg every 4 h for 17 doses	1330 mg/kg

acetaminophen overdose [7]. In the USA an oral formulation had to be used. The UK regimen developed by Prescott and colleagues in Edinburgh was a 20.25 h IV protocol, delivering 300 mg/kg of NAC over the duration of treatment, with 150 mg/kg given in the first 15 min, 50 mg per kilogram over 4 h, and 100 mg/kg over 20 h. The regimen used in North America was 140 mg/kg initially followed by 70 mg/kg every 4 h for 17 doses [8]. Case series using longer intravenous [122, 123] and shorter oral regimens have also been reported. The standard North American IV regimens subsequently developed use a 21 h protocol, with the first infusion, similar in dose to the original Prescott regimen, being given over 1 h (Table 2). Recently in the UK regulatory decision has been made to also move to the 1 h initial IV dose [101]. In view of the relatively low lipid solubility of acetaminophen and the relationship between NAC dose and adverse event risk some authorities advise using a maximum weight of 110 kg in obese patients and pregnancy when calculating NAC dose [124]. A recent study in comparing patients with weights above and below 100 kg did not show an excess of ADRs in the heavier patients [125], although detected rates of ADRs were very much lower than seen in prospective studies, throwing some doubt on the validity of these findings.

The Danish approach to acetaminophen poisoning has been very different to anywhere else worldwide. They have historically treated all patients with paracetamol excess [126]. This is not a cost-effective approach, and risks excess NAC anaphylactoid effects in patients with low acetaminophen concentrations [127].

NAC is effective if given early after acetaminophen ingestion but is recognized to lose efficacy the longer the interval between acetaminophen dose and treatment (II-2) [8]. No parallel study

has been done comparing oral and IV antidote use, but comparing historical groups there is no strong evidence of the major difference in the efficacy of different regimens (II-2) [128]. There is a theoretical risk, based on calculations of the potential hepatic production of NAPQI in acetaminophen overdose, that the dose of NAC in the current IV regimen is less than would be required to provide full antidote efficacy in very large overdoses of acetaminophen (e.g., 4 h acetaminophen concentrations >600 mg/L) (III) [9]. Some toxicologists advise a doubling of NAC in such patients; however, this practice is controversial since the metabolic interaction between antidote and acetaminophen reactive metabolites at these concentrations is unknown. Potential confounders include substrate inhibition within the liver and saturation of the capacity to generate glutathione from NAC.

Adverse effects to NAC have been recognized since the antidote was first used. Major adverse effects seen are nausea and vomiting and anaphylactoid reactions. Death has been reported, but this is most likely due to overdosage with IV NAC due to miscalculation and confusion in the dosage form in the 1980s. Rates of adverse reactions are variously reported and are likely to depend on the methods used to ascertain them [129]. Prospective close monitoring results in far higher estimates than retrospective analysis [130]. Nausea and vomiting requiring treatment with antiemetics seems to occur between 20% and 30% of patients [127]. Symptoms of nausea are far more frequent, reaching 70% in prospective studies (I) [131]. The incidence of nausea and vomiting does not seem related to the quantity of acetaminophen ingested. In contrast, anaphylactoid reactions are inversely related to the plasma concentration of acetaminophen (II-3) [132, 133]. Thus, recent changes in the UK to treat patients with lower plasma concentrations of acetaminophen have resulted in increasing risk of adverse effects from the antidote [133]. Anaphylactoid reactions seem due to histamine release [130] and can be treated successfully using antihistamines, with the addition of beta-receptor agonists when bronchospasm is present. As the mechanism is not immunological there is no necessity to use corticosteroids in managing

this reaction. In severe cases adrenaline may be required, and in patients with hypotension additional fluid should be given intravenously. Nausea and vomiting should be treated with a standard antiemetic, although it would seem prudent to avoid ondansetron in view of the signal of toxicity when used in acetaminophen overdose [131].

A recent clinical trial studied the effect of a shorter, 12 h, IV protocol delivering 100 mg/kg NAC over 2 h and 200 mg/kg over 10 h. This study was primarily to examine effects on adverse reactions to NAC and was not powered to assess relative efficacy against the 20.25 h regimen used as control; however, it suggested no lack of inferiority of the shorter regimen [131]. Further work using this protocol is needed before it can be used widely in clinical practice; nevertheless, it suggests potentially even shorter treatment may be possible in selected patients. This is perhaps not surprising bearing in mind the short half-life of acetaminophen at therapeutic dose [32].

Most patients who are treated worldwide will now receive a standard 21-h intravenous protocol of NAC. The oral regimen should only be considered in those in whom IV access is impossible or in situations where IV therapy is unavailable. Methionine [107], an alternative oral antidote, seems of less efficacy based on historic studies, but is still used in some countries.

Blood samples need to be taken at the end of the treatment period to ensure that the patient is fit to discharge. Mandatory tests include measurement of transaminase (usually ALT), serum creatinine, and prothrombin time. Many clinicians will also wish for a repeat acetaminophen concentration to ensure that the drug has been eliminated. In the USA for patients who have taken a large overdose, or who have a prolonged half-life, such measurement of acetaminophen concentrations prior to discontinuing therapy is essential, and the standard of care, to ensure that NAC is not stopped while significant levels of acetaminophen are still circulating.

Interpretation of blood tests post treatment is relatively straightforward. The rate of rise in transaminase is related to the severity of toxicity, and therefore very small perturbations in measurements are normally insignificant clinically

[134]. Many clinicians will use a doubling in ALT to determine whether hepatotoxicity is likely. Acetylcysteine interferes with the measurement of INR [108, 135], and thus a small rise (e.g., to less than 1.4) with a normal ALT can usually be ignored. Acetylcysteine continuation should be considered in those with a rising ALT, or other features suggesting impending liver failure. Hepatotoxicity in acetaminophen poisoning was traditionally defined as an ALT over 1000 IU/L [107]. This cutoff is rather arbitrary, and many patients will recover without liver unit care at this concentration. Acetylcysteine can be discontinued when ALT starts to improve and INR begins to recover. Extensive clinical experience by the author in several thousand cases has shown that it is not necessary to treat until normal values have returned. Jaundice is a late feature in acetaminophen-induced liver failure, and measurement of bilirubin is of most value in the management of acute liver failure.

Interpretation of serum creatinine is also affected by the use of acetylcysteine since it impairs the synthesis of creatinine. Rising creatinine above 10% of baseline should therefore be regarded as potentially indicating onset of renal impairment. In this circumstance it is prudent to recheck the blood test since patients with renal damage may not show the full clinical syndrome of renal failure until 3–5 days after acetaminophen overdose.

In patients who go on to develop liver injury it is important to continue to administer NAC, as there is evidence that this is protective in hepatic coma (II-2) [136, 137]. Monitoring progress requires regular measurement of liver and renal function and clotting tests. As liver injury develops synthesis of clotting factors is impaired, and those with the shortest half-life (factors V and VII) disappear most rapidly. Measurement of the concentrations of individual clotting factors may therefore be considered in patients with incipient hepatic failure in an attempt to estimate severity.

Patients who develop renal injury and hepatic injury in combination seem to have a far worse prognosis, and those who present with renal injury have a high mortality (II-3) [15]. It is sensible to discuss patients with significant hepatic damage,

for example, rapidly rising ALT, clotting disturbance and renal injury, with a liver unit as some patients may go on to require hepatic transplantation. The King’s College criteria are widely used as an assessment tool in this situation.

Liver Transplantation and Management of Fulminant Hepatic Failure

In patients in whom ALF develops from acetaminophen toxicity, the most pressing question is whether orthotopic liver transplantation (OLT) is necessary for their survival. Patients need to be discussed early with a local liver unit, and transfer of the patient will be determined by local criteria. In patients with severe coagulopathy, renal failure, acidosis, hypoglycaemia, and encephalopathy care in a liver unit is mandatory. Most hepatologists will consider rate of disease progression, patient age, and laboratory markers. Thus a prothrombin time that is greater in seconds than the hours after overdose is used in the UK as a marker of poor prognosis. In patients with overdose there may also be psychological aspects to consider in relation to managing patients post transplant that may influence decision to transplant.

To date there is little evidence that artificial liver devices have a benefit in this clinical situation. Transplantation is therefore a key treatment methodology in severe cases. To make an informed recommendation with regard to OLT it is necessary to consider the natural history of patients who do not undergo transplantation, as well as the utility of prognostic indicators. Most patients in whom ALF develops from acetaminophen toxicity survive and fully recover without transplantation. The King’s College group reported their experience in 1255 patients with ALF and 908 with acute liver injury (ALI) from acetaminophen toxicity treated at their center between 1973 and 2008 [71]. Those with ALF were older, more likely to be female, and to have renal injury at admission to the liver unit. The majority survived without OLT, and only 147 were transplanted, survival from which improved significantly over the 35 y period of the study to the order of 80% [71]. The presence of overt encephalopathy was strongly associated with poorer outcome. The capacity for liver

recovery is better in acetaminophen poisoning than other causes of acute liver failure [138].

The search for highly sensitive and specific prognostic factors continues. Reliable indicators are critically important because patients may have sudden clinical deterioration and die before transplantation can take place. The window of opportunity for successful transplantation is often less than 24 h. In contrast, transplantation should be avoided in patients expected to survive because liver function recovers completely and transplantation unnecessarily dooms the patient to a lifetime of immunosuppressive therapy.

Auxiliary transplantation is a technique in which a partial liver graft is placed while the patient’s liver recovers, and which can then be allowed to reject or be removed. It seems attractive in theory but is technically demanding and experience is limited in acetaminophen overdose [138].

Prognostic Indicators

Several groups have studied prognostic indicators to develop criteria for transplantation. The most widely published transplant criteria were derived at the King’s College Hospital liver unit in London (Table 3). According to these criteria, patients should be considered for liver transplantation if their arterial pH is less than 7.3 at 24 h or later after acetaminophen ingestion despite fluid resuscitation and treatment with sodium bicarbonate or if they have a combination of grade III or IV encephalopathy, serum creatinine level higher than 3.4 mg/dL (300 μmol/L), and INR longer than 6.5 [138]. These criteria were originally derived from 310 acetaminophen-poisoned patients studied between 1973 and 1985 [139]. They were later validated by the same investigators in a group of 120 patients treated between 1990 and

Table 3 Original King’s College Criteria for Transplantation

PH < 7.25 24 h after overdose despite fluid resuscitation and sodium bicarbonate
Concurrent presence of grade III-IV encephalopathy, creatinine >3.4 mg/dL (300 μmol/L), and INR more than 6.5

1994. The positive predictive value of these criteria for a fatal outcome is 88%, and the negative predictive value is 65% [140]. An alternative scoring system is the MELD score suggested as an improvement, and more recently the Acute Liver Failure Group Index has been used. The latter includes coma grade, laboratory results (INR, bilirubin, and phosphorus) and an apoptosis marker (M30) and is reported as an improvement on the Kings College Hospital criteria [141]. Present UK criteria for emergency transplantation in acetaminophen poisoning are

1. pH < 7.25 despite fluid resuscitation
2. Severe coagulopathy (INR > 6.5) and renal failure (anuria or serum creatinine > 300 μ mol/L) and grade 3–4 encephalopathy
3. Serum lactate > 3.5 on admission or > 3.0 after fluid resuscitation
4. Any two criteria from category 2 combined with clinical deterioration in the absence of sepsis [141]

O'Grady has also suggested some criteria when transplantation is contraindicated, and these include compromised brainstem function, invasive fungal infection, rapid increasing need for inotropes, and severe pancreatitis [141]. Long-term quality of life is impaired in those receiving transplants, further emphasizing the need to carefully assess the use of this therapy in acetaminophen-induced liver failure [142].

Psychiatric Assessment Before Orthotopic Liver Transplantation

Psychiatric assessment for transplant feasibility is an essential aspect of the transplantation evaluation [143]. OLT is a major operative procedure, and its ultimate success is in part dependent on the transplant recipient's compliance with post-transplant care, including the need for lifelong immunosuppressive therapy. Although a suicide attempt or a history of ethanol or substance abuse by itself does not preclude transplant suitability, skilled assessment by a psychiatrist who has a close working relationship with the transplant

team is essential to determine the likelihood of long-term post-transplant compliance. Ongoing substance abuse is a probable contraindication to this procedure. The long-term medical and psychiatric outcomes in those with hepatic transplantation for acetaminophen overdose seem similar to other groups [144].

Medical Management

Aggressive medical management is warranted for patients with ALF in an attempt to stabilize the patient and prevent further deterioration. Medical issues that arise include treatment of coagulopathy, renal failure, encephalopathy, cerebral edema, sepsis, cardiovascular collapse, metabolic derangements, and respiratory failure.

Coagulopathy

Coagulopathy will develop in many patients as demonstrated by an increased PT and INR. However, given the use of PT/INR as an indicator for the need for liver transplantation, many recommend that vitamin K and factor replacement with fresh frozen plasma be withheld unless the patient has frank bleeding or requires an invasive procedure such as an arterial line, central line, or insertion of an intracranial pressure monitor. The efficacy of vitamin K therapy in patients with acetaminophen-induced hepatic synthetic dysfunction is of uncertain value, and as the primary problem is failure to synthesize clotting factors this is not unexpected. Active hemorrhage, most often upper gastrointestinal bleeding, necessitates treatment with fresh frozen plasma and red blood cell transfusion as needed. The use of H₂-blockers may reduce the risk of such bleeding.

Renal Failure

Renal failure occurs in more than 75% of cases of ALF from acetaminophen overdose and is an indicator of adverse outcomes [15]. Decreased urine output may be the sign of acute renal failure, hepatorenal syndrome, and/or undertreated hypovolemia. Fluid resuscitation in these cases

may inadvertently lead to fluid overload and pulmonary edema. Hemodialysis may be warranted, although the criteria for initiation are not well established [120]. Venovenous hemofiltration is an alternative therapy and regularly used to support renal and metabolic complications. Low-dose dopamine (2–4 $\mu\text{g/kg/h}$) may improve renal perfusion and function. Nephrotoxic drugs should be avoided, and dosing of medications undergoing significant clearance by the kidney should be adjusted for renal insufficiency.

Encephalopathy

Because the most common cause of death in patients with ALF is intracranial hypertension, with resultant brain herniation, the onset of hepatic encephalopathy is an ominous finding. Blood ammonia concentrations are usually elevated, but the degree of ammonia elevation correlates poorly with the extent of encephalopathy. Computed tomography of the head should be performed if the patient's mental status deteriorates suddenly to evaluate for evidence of intracranial hemorrhage or cerebral edema.

Sepsis and Shock

Patients with ALF who survive the first 4–5 days after an acute overdose remain at risk for complications of systemic inflammatory response syndrome (SIRS), sepsis, and hemodynamic collapse. SIRS is associated with worsening encephalopathy and a poorer prognosis. Susceptibility to infection, both bacterial and fungal, appears to be as common in ALF secondary to acetaminophen overdose as in other etiologies [145, 146]. Infections are thought to be the direct cause of death in around 20% of patients with ALF. The most common sites of infection are the respiratory tract, urinary tract, and blood. Bacteremia may be a direct result of seeding from a catheter or from decreased integrity of gastrointestinal mucosa. Endotoxemia, macrophage activation, and cytokine and tumor necrosis factor release may all occur and lead to a clinical

condition resembling septic shock. Because the only early sign of infection may be worsening encephalopathy or renal dysfunction, a high index of suspicion for infection, including daily cultures of blood, urine, and other fluids, has been recommended. The administration of broad-spectrum antibiotics is warranted if there is evidence of fever or other signs of infection. Antifungal agents may also need to be given to patients who do not respond rapidly to antibiotics. The use of prophylactic antibiotics and antifungals in these patients remains controversial.

Hemodynamic collapse and sudden death may also occur in patients with ALF secondary to acetaminophen overdose. Measurement of central venous pressure may prove useful to optimize fluid management. Continuous cardiac monitoring is essential. Norepinephrine or epinephrine infusions may be used to keep mean arterial pressure above 60 mmHg.

Hypoglycemia

Hypoglycemia from impaired gluconeogenesis and decreased hepatic glycogen stores is one of the most significant metabolic derangements in patients with ALF. Hypoglycemia develops in more than 40% of these patients, and therefore frequent glucose monitoring is critical. Patients with hypoglycemia may require 10% dextrose infusions. The delivery of more concentrated glucose solutions through a central line may be necessary in patients with refractory hypoglycemia. Metabolic acidosis should be aggressively corrected with sodium bicarbonate infusion. Hypophosphatemia is also common and should be corrected.

Sedation

Careful consideration must be given to which agents should be used for sedation in patients with ALF. No controlled studies have been conducted that address this issue. If drugs are used, an agent that does not have active metabolites may be preferable. Offset of drug effect may be prolonged.

Criteria for ICU Discharge in Acetaminophen Poisoning*Resolution of major metabolic abnormalities**Improving coagulopathy**Resolving encephalopathy***Special Populations****Pregnant Patients**

Acetaminophen is the preferred analgesic/antipyretic during pregnancy because it is safe at therapeutic doses and there is no evidence that it is teratogenic [147]. However, while there is potential for fetal toxicity after a maternal overdose the major determinant of fetal outcome is the health of the mother. A Scandinavian study suggested an excess of spontaneous abortion in those with a range of acute overdoses in pregnancy and 3 months before conception (13 acetaminophen). Spontaneous abortion was 10% more frequent, but there was no excess in malformations. Acetaminophen freely crosses the placenta, and the fetal liver is capable of elaborating detectable amounts of NAPQI by about 14 weeks' gestation [148]. NAC also crosses the placenta; after a maternal overdose it was found in the cord blood of delivered infants ($n = 4$) at concentrations equivalent to those in maternal blood [149]. Acetaminophen overdose in pregnancy has been reported to result in fetal morbidity and mortality; treatment delay is significantly correlated with fetal loss [148, 150]. Pregnant women who have ingested a potentially toxic amount of acetaminophen should receive treatment as per nonpregnant patients. It seems prudent to use the patient's actual weight when determining the dose of NAC (to a maximum of 110 kg). Other interventions such as emergency cesarean section are not usually warranted. However, cesarean section may be contemplated for near-term infants if the mother has substantial acetaminophen-induced hepatic necrosis. Liver transplantation has been reported successfully in pregnancy in the second trimester, though with fetal loss in this case [151].

Neonatal Patients

Neonates have been safely and effectively treated with IV NAC. Data from a 55-day-old infant born at 29 weeks of gestation indicate slower metabolism in preterm infants in keeping with kinetic predictions [152]. Care must be taken to not give excessive free water, which can result in hyponatremia, and specific regimens for managing infants are published: for example, using 3 ml/kg/h of 50 mg/ml NAC for 1 h followed by 2 ml/kg/h of 6.25 mg/ml NAC for 4 h and then 1 ml/kg/h NAC of 6.25 mg/ml for 16 h, normally given in either 5% glucose or 0.9% sodium chloride [101, 124].

Patients with Myopathies

There are data suggesting that children with myopathies are at greater risk of liver damage from acetaminophen. Both children in this report were in intensive care, one post operatively and the other having a chest infection. The reason for the toxicity is unclear; starvation is an obvious risk factor, and both children were under 60 kg in weight (40 and 55 kg) [66]. Particular care is needed in use and dose of acetaminophen to avoid toxicity in such patients.

Key Points in Acetaminophen Poisoning

1. IV NAC is a highly effective antidote when given shortly after an acute overdose and is the treatment of choice.
2. Decision to treat should be based on a nomogram assessing concentration of acetaminophen taken at least 4 h after a single ingestion.
3. In patients presenting more than 8–10 h after a single ingestion history of ingested dose should be used to assess need for therapy with NAC.
4. In those taking multiple overdoses, or therapeutic excess, the decision to treat is based on history of dose ingested, usually

(continued)

in the last 24 h, on blood results or on presence of symptoms suggestive of liver injury.

5. History of dose ingested correlates well with the plasma concentration of acetaminophen in most patients. If in doubt (e.g., the timing or amount of ingestion) err on the side of prompt treatment with NAC, and revise treatment once blood tests are available.
6. Oral NAC may be used in patients in whom IV therapy is not possible, but care needs to be taken in preventing vomiting.
7. Time to treatment is a key determinant in patient outcome, and delay should be avoided, particularly more than 10 h after acetaminophen ingestion.
8. Most patients with significant hepatotoxicity (AST >1000 IU/L) and coagulopathy after acetaminophen overdose survive without liver transplantation.
9. Presence of acute renal injury at presentation is a marker of poor prognosis.
10. It is essential to check blood results after a course of NAC, and only discharge patients if these are within acceptable limits.
11. Further doses of NAC are indicated in those with abnormal liver function.
12. Patients who survive an acetaminophen overdose have no residual liver damage.
13. Unless clinically indicated, fresh frozen plasma and vitamin K should not be given if the patient has an elevated PT because the PT is an important prognostic indicator.
14. NAC can decrease morbidity and mortality when administered to patients with fulminant hepatic failure after an acute acetaminophen overdose.
15. Selective use of liver transplantation as a treatment modality for patients with fulminant hepatic failure from acetaminophen toxicity, especially in the presence of acidemia, may prove beneficial.

Introduction

Methotrexate (amethopterin, 4-amino-10-methylpteroglutamic acid) has been a widely used folate antagonist, initially as an antineoplastic agent, and later on as an anti-inflammatory and immunomodulation agent. Aminopterin was the first folate antagonist successfully used for induction of temporary remission in acute leukemia in children [1]. Methotrexate, a safer related agent of aminopterin, replaced it as an antileukemic drug [2]. Since then, methotrexate has been increasingly used as a monotherapy and in combination with other antineoplastic agents for a variety of hematologic and non-hematologic malignancies in children and adults. Its anti-inflammatory and immunomodulation properties were found to be also efficacious in a broad range of dermatologic, rheumatologic, and other disease states (e.g., ectopic pregnancy, graft vs. host disease). The main clinical applications of methotrexate are shown in Table 1 [3].

There are no comprehensive epidemiological data on the incidence, circumstances, and severity of methotrexate overdose and poisoning. However, it may be deduced from the available literature that methotrexate poisoning can occur in the following settings:

1. High-dose methotrexate (HD-MTX) administered to cancer patients. This regimen involves high doses of methotrexate (usually ≥ 500 mg/m²) that can lead to severe toxicity and death, even if no medication error occurred; the mortality associated with HD-MTX before using methotrexate drug monitoring and adjusted dose of folinic acid (Leucovorin) was 4.6–13.6%. HD-MTX-induced renal failure can still cause substantial morbidity and mortality [4–6].
2. Low-dose methotrexate (LD-MTX) used for nonmalignant diseases such as rheumatoid arthritis and psoriasis. It is considered a relatively safe treatment. However, medication

Obstetric		Termination of pregnancy

errors (iatrogenic or patient noncompliance) can lead to toxicity and even death, depending on dose, risk factors, delay in diagnosis, and adequacy of treatment [7, 8].

3. Unintentional overdoses, mainly in children not treated with methotrexate; infrequently reported [9, 10].
4. Attempts at self-harm; rarely reported [9]. The National Poison Data System (NPDS) of the American Association of Poison Control Centers refers to antineoplastic agents without specifying methotrexate. In addition, the NPDS does not list methotrexate or antineoplastic agents as a category or substance with a large number of fatalities [11].

Most methotrexate-induced toxicities are related to therapeutic regimens, mainly HD-MTX, which are managed by hemato-oncologists without medical toxicology or poison center consultation. The mainstay of the management of methotrexate poisoning is appropriate dose tailoring, prevention, identification of risk factors, early detection of errors, vigorous hydration, urinary alkalinization, rescue with folinic acid, enzymatic cleavage of methotrexate with glucaripidase (carboxypeptidase G₂), and extracorporeal enhanced elimination [6, 12].

The molecular structures of folic acid, folinic acid, and methotrexate are shown in Fig. 1.

Clinical Pharmacology

The pharmacokinetics of methotrexate is characterized by striking interpatient variability.

Absorption: The reduced folate carrier protein (RFC1) actively transports methotrexate. This is a cell surface transmembrane protein and a bidirectional transporter of reduced folates and methotrexate. It is highly expressed in the colon, kidney, brain, thymus, and spleen and moderately in the small intestine, liver, bone marrow, lung, and testes. Several ATP-binding cassette (ABC) transporters (e.g., ABCB1, ABCC1, ABCB2, ABCG2) are located on the apical side of various epithelial and endothelial cells, hepatocytes, kidneys, and in lymphocytes. They are responsible to

efflux carrier-mediated transport of methotrexate. All these transporters are subjected to pharmacogenetic variability [13, 14]. Oral methotrexate doses of less than 30 mg are absorbed rapidly and almost completely. Intestinal absorption is active and saturable; therefore, high doses should be given parenterally in order to achieve effective plasma concentrations [15]. Bioavailabilities of 90% and 50% were reported after oral doses of less than 30 mg/m² and 30–80 mg/m², respectively [16]; a plateau was reached at doses of 25–50 mg [17]. Another study showed bioavailability to be significantly lower following doses higher than 40 mg/m² compared with lower doses, 17.5% versus 42%, respectively [18]. However, variable bioavailabilities of 23–95% were reported in children treated with oral methotrexate doses of less than 28.1 mg/m² [19]. Oral doses of 80 mg/m² or higher are incompletely absorbed resulting in plasma concentrations less than one-tenth of that seen after IV administration [16, 17, 20, 21]. The mean oral bioavailability of methotrexate in pediatric patients with inflammatory bowel disease was 84 ± 38%. Interpatient variability was similar between subcutaneous and oral administration. This finding is similar to that found in other disease states [22]. Bioavailability was substantially higher after intramuscular administration than oral and less variable [18].

Peak plasma concentrations after oral doses of less than 20 mg/m² are 0.3–2.2 µmol/L at 1.5–2.5 h [20, 21]. In pediatric patients, oral doses of 6.3–30 mg/m² resulted in a significant interindividual variability in peak concentrations (0.27–1.1 µmol/L) and time to peak (1–5 h) [19, 23]. Treatment with 50–250 mg/kg methotrexate as a 6-h infusion was associated with peak levels between 100 and 1,000 µmol/L [24]. Methotrexate doses of 12 g/m² IV resulted in a C_{max} of >1,000 µmol/L in 96% of patients [25]. In another study of patients with HD-MTX (300 mg/m² to 12 g/m²), plasma methotrexate concentrations at 24 and 48 h after the start of infusion were 0.66 µmol/L and 0.12 µmol/L, respectively; 7-hydroxy-methotrexate (the main active and toxic metabolite) concentrations were 2.52 µmol/L and 0.72 µmol/L, respectively [26].

Fig. 1 Molecular structure of folic acid, folinic acid, methotrexate, and its main metabolites

Distribution: The protein binding of methotrexate is 50–70%, primarily to albumin [16]. Distribution half-life is 0.75 h [27]. Initial volume of distribution is 0.18 L/kg, and

the steady-state volume of distribution is 0.4–0.8 L/kg [28–30]. A population kinetic study found a volume of distribution of the central compartment of 23 L; the volumes of

the first and second peripheral compartments were 185 and 5.34 L, respectively [26].

Elimination: Methotrexate is eliminated mainly in its unchanged form through the kidneys by glomerular filtration together with tubular reabsorption and secretion (50–90% within 48 h, mostly within 8–12 h) [20, 21, 26]. It was suggested that tubular reabsorption and secretion are also saturable [31, 32]. Inadequate hydration, low urine flow and pH, and concomitant nephrotoxic drugs can affect renal clearance of methotrexate resulting in toxicity. A small amount of unchanged methotrexate (less than 10%) undergoes biliary excretion and enterohepatic circulation [33].

Metabolism becomes more important in HD-MTX. Methotrexate undergoes liver and intracellular metabolism; it is also partially metabolized by intestinal flora after oral administration. Hepatic aldehyde oxidase metabolizes about 10% of the methotrexate dose via hydroxylation to 7-hydroxy-methotrexate. This metabolite possesses 1/100–1/200 of the inhibitory dihydrofolate reductase (DHFR) activity of methotrexate [31, 32, 34–36]. Within 12–24 h of the start of HD-MTX, the plasma concentration of 7-hydroxy-methotrexate exceeds that of methotrexate. Both methotrexate and 7-hydroxy-methotrexate undergo intracellular polyglutamation by Folypolyglutamyl synthase, causing its retention and leading to amplified cytotoxicity [6, 37, 38]. Methotrexate is also metabolized to 2,4-diamino- N^{10} -methylpteroic acid (DAMPA), an inactive metabolite (less than 5% of dose). It is believed that DAMPA is formed from hydrolysis of methotrexate excreted into the intestinal tract by bacterial carboxypeptidase. Eventually, DAMPA is reabsorbed, accounting for less than 5% of the total methotrexate dose excreted in urine [6, 20, 38–41].

Population pharmacokinetics showed methotrexate and 7-hydroxy-methotrexate clearances to be 147.5 and 33.3 mL/min, respectively [26]. The range of methotrexate clearance reported was 99.1–156.7 mL/min [42, 43]. A threefold variation in plasma methotrexate concentrations was found after a dose of 1 g/m² IV, suggesting patient variability in elimination [44]. Methotrexate clearance

was significantly lower in infants less than 6 months old compared with infants 7–12 months old, 89 ± 32 mL/min/m² and 111 ± 40 mL/min/m², respectively [45].

Plasma methotrexate concentrations fell in a bi-exponential curve corresponding to elimination half-lives of 2 and 10.4 h [24]. Other studies suggested a triphasic disappearance of methotrexate from plasma following intravenous administration. The initial (distribution) half-life was 0.75 ± 0.11 h, second half-lives were 2.06 ± 0.16 , 3.49 ± 0.55 , and 2.0–3.4 h (representing mainly renal clearance), and terminal half-life was 10.4 ± 1.8 h (representing tissue redistribution) [16]. Another study also showed that a linear three-compartment model with first order elimination from the central compartment best described methotrexate concentration-time data. 7-hydroxy-methotrexate followed a linear two-compartment model with first order elimination from the central compartment [26]. In osteosarcoma patients on HD-MTX, non-compartmental analysis and population pharmacokinetic modeling showed that median methotrexate late elimination half-life was 4.02 h [42]. Elimination half-life after oral administration was 4–6 h [19, 20]. In children on weekly LD-MTX, median elimination half-life was 1.7 h [46].

The main pharmacokinetic characteristics of methotrexate are summarized in Table 2.

Cerebrospinal fluid (CSF) concentrations after HD-MTX are about 1–10% of the corresponding plasma concentrations. CSF concentrations between 0.1 and >10 μ mol/L were measured after a 24-h infusion of 500 mg/m² and a 7.5 g/m² IV bolus, respectively [47–50]. Methotrexate is pumped out of the CSF by ABC transporters [20].

Ascites or effusions may serve as a reservoir from which methotrexate can redistribute. The concentrations of methotrexate in third space collections are usually 10% of the plasma concentrations. The volume and consistency of these fluids can affect the elimination of methotrexate from such spaces, resulting in much higher levels and prolonged cytotoxic plasma concentrations. Methotrexate doses higher than 250 mg/m² are

Table 2 Pharmacokinetic parameters of methotrexate

Pharmacokinetic parameter	
Systemic oral bioavailability	17.5–95% Variable and dose dependent Highest if $<30 \text{ mg/m}^2$, lowest if $>80 \text{ mg/m}^2$
C _{max} oral (6.3–30 mg/m^2)	0.27–1.1 $\mu\text{mol/L}$
T _{max} oral (6.3–30 mg/m^2)	1–5 h
C _{max} HD-MTX (IV 12 g/m^2)	$>1,000 \mu\text{mol/L}$
C _{max} HD-MTX (IV 50–250 mg/kg)	100–1,000 $\mu\text{mol/L}$
Protein binding	50–70%
Volume of distribution, steady state	0.4–0.8 L/kg
Clearance	99–157 mL/min
Renal elimination	50–90% within 48 h
Elimination half-life, terminal (HD-MTX)	10.4 h

more likely to be associated with these effects [51–53].

Pharmacokinetic Drug–Drug Interactions

In patients on HD-MTX (300 mg/m^2 to 12 g/m^2), population pharmacokinetics showed that concurrent use of benzimidazoles (e.g., omeprazole, lansoprazole) caused a significant 3.03 (range 2.19–4.19) and 2.1 (range 1.5–2.95) increases in plasma methotrexate concentrations at 24 and 48 h, respectively; methotrexate clearance significantly decreased by 27% [26]. Decreased elimination of methotrexate by benzimidazoles may due to inhibition of methotrexate transport by the drug transporter ABCG2 (BCRP) [54].

Prior administration of nonsteroidal anti-inflammatory drugs (e.g., diclofenac, ibuprofen) increased plasma methotrexate concentrations by 1.26 (range 0.84–1.91) and 1.34 (range 0.84–2.13) at 24 and 48 h, respectively; plasma clearance decreased by 16%. Similar changes

were reported for 7-hydroxy-methotrexate; all changes were significant [26]. Nonsteroidal anti-inflammatory drugs exert their interaction with methotrexate via decreased renal blood flow.

The main mechanisms of pharmacokinetic drug interaction include decreased renal tubular secretion (e.g., by piperacillin/tazobactam, salicylates, probenecid, trimethoprim–sulfamethoxazole, ciprofloxacin), protein binding displacement (e.g., by trimethoprim–sulfamethoxazole), and reduced glomerular filtration [26, 55, 56].

Therapeutic Drug Monitoring

Early studies showed that plasma methotrexate concentrations of 0.9 $\mu\text{mol/L}$ or higher 48 h after the start of high-dose infusion (50–250 mg/kg) were associated with myelosuppression and mucositis [24]. Therefore, plasma methotrexate concentrations and serum creatinine should be determined during HD-MTX therapy in order to identify patients at risk and guide administration of high-dose folinic acid rescue, enzymatic cleavage with glucaridase, and enhanced elimination. It is important to measure plasma methotrexate concentrations at the time intervals dictated by the HD-MTX protocol used. It is usually recommended to monitor plasma methotrexate concentrations 24, 48, and 72 h after the start of a 4-h HD-MTX infusion, aiming to reach target concentrations of ≤ 5 –10, ≤ 1 , and $\leq 0.1 \mu\text{mol/L}$, respectively [6, 57, 58]. If a 24-h infusion is administered, it is recommended to determine plasma methotrexate concentrations at 42 and 66 h after the start of the infusion; target concentrations are <0.5 –1 and $<0.1 \mu\text{mol/L}$, respectively [58].

It was suggested to continue folinic acid until plasma methotrexate concentrations are less than 0.01 $\mu\text{mol/L}$, the methotrexate threshold for in vivo inhibition of DNA synthesis in bone marrow and gastrointestinal epithelium [24, 59]. More recent studies suggest that concentrations of less than 0.05–0.1 $\mu\text{mol/L}$ allow discontinuation of folinic acid [6].

Pathophysiology

Methotrexate is a folate antagonist. Therefore, its mechanisms of action and toxicity are better understood by knowing the metabolic pathways of folic acid (Fig. 2).

Folate is transported into the cells where it is converted to tetrahydrofolate (FH₄). It participates in a series of metabolic reactions necessary for pyrimidine and purine syntheses, involving the enzymes dihydrofolate reductase (DHFR), methionine synthase (MS), thymidylate synthase (TS), aminoimidazole carboxamide

ribonucleotide transformylase (AICRT), and glycinamide ribonucleotide transformylase (GARFT). Folates undergo polyglutamation inside the cell, which increases their intracellular store due to reduced efflux and increased uptake [6, 26, 60–63].

The main intracellular sites of action of methotrexate and folinic acid are shown in Fig. 3.

Methotrexate is actively transported into cells via the reduced folate carrier (RFC1, SLC19A1). When methotrexate extracellular concentrations exceed 20 μmol/L, passive diffusion across the cell membrane takes place. ATP-binding cassette

GARFT – glycinamide ribonucleotide transformylase; MS – methionine synthetase; MTHFR – methylene tetrahydrofolate reductase; SAH – S-adenosylhomocysteine; SAM – S-adenosylmethionine; TS – thymidylate synthetase

Fig. 3 Intracellular sites of action of methotrexate and folinic acid. ABC – ATP binding cassette; AICRT – aminoimidazole carboxamide ribonucleotide transformylase; DHFR – dihydrofolate reductase; GARFT – glycinamide ribonucleotide transformylase; GGH – glutamyl hydrolase; FH_2 – dihydrofolate;

FH_4 – tetrahydrofolate; FPGS – folypolyglutamyl synthetase; DAMPA – 2,4-diamino-N-methylptericoic acid; MTX – methotrexate; MTXpglu – methotrexate polyglutamate; SLC19A1 – reduced folate carrier (RFC); TS – thymidylate synthetase; Folic acid – N^5 -formyl tetrahydrofolate (Leucovorin)

(ABC) transporters (mainly ABCC1-4, ABCG2) pump methotrexate out of the cells. Intracellular methotrexate (as well as folate) undergoes polyglutamation to an active form (methotrexate polyglutamate; MTXpglut) which is retained in the cells for prolonged periods of time. Polyglutamation increases the affinity of methotrexate for vulnerable enzymes. The longer the polyglutamated tail (>5 glutamic acid residues) is, the diffusion out of cells is slower, and the affinity to the inhibited enzymes is stronger. Hydrolysis by γ -glutamyl hydrolase (GGH) reverses polyglutamation of methotrexate. This results in cellular efflux of methotrexate and short-chain MTXpglut.

Three enzymes are inhibited by methotrexate and MTXpglut:

1. DHFR. The binding of methotrexate to DHFR is stoichiometric and competitive; 95% inhibition is required to stop FH_4 synthesis. This will result in FH_4 depletion and decreased synthesis of thymidylic acid and inosine monophosphate involved in pyrimidine and purine synthesis,

respectively. The reduced concentrations of FH_4 and N^5 -methyl FH_4 resulting from inhibition of DHFR also cause accumulation of homocysteine and its metabolites and excitatory amino acids [excitatory agonists of N -methyl-D-aspartate (NMDA) receptors]. The decreased supply of methionine eventually results in reduced synthesis of neuronal myelin sheath.

2. Thymidylate synthase. The inhibition of thymidylate results in reduced pyrimidine synthesis.
3. AICRT and GARFT. Purine synthesis diminishes due to inhibition of these enzymes.

The net result is blockade of DNA, RNA, and protein synthesis through both direct enzyme inhibition and depletion of FH_4 [20, 59, 62, 64–77].

The severity and type of methotrexate cytotoxicity depend on both concentration and duration of exposure. Brief exposure to high concentrations (mmol/L for minutes or hours) may be tolerated, but may also lead to acute renal, liver, and

central nervous system (CNS) toxicity. Low concentrations for a prolonged period (e.g., 0.05–0.1 $\mu\text{mol/L}$ for 24–48 h) can result in life-threatening toxicity, including bone marrow and gastrointestinal effects [6, 26, 59]. Polyglutamation occurs when cells are exposed to methotrexate concentrations of $\geq 2 \mu\text{mol/L}$ for ≥ 6 h, explaining the greater incidence and severity of toxicity associated with HD-MTX [78, 79]. Following HD-MTX, 7-hydroxy-methotrexate is formed; it has about 1/100–1/200 of the DHFR inhibitory activity of methotrexate [31, 32, 34–36]. 7-hydroxy-methotrexate is also polyglutamated; this form retains in the cells for prolonged periods of time, resulting in enhanced toxicity [6, 37, 38].

Supplemental folate is reduced intracellularly to FH_4 by DHFR. Methotrexate-induced inhibition of DHFR explains why supplemental folate cannot be used as an antidote for methotrexate toxicity. Folic acid was found to decrease kidney reabsorption of methotrexate in an experimental study [80].

The mechanism of action of folinic acid is discussed in the “[Treatment](#)” section. The clinical pharmacology of folinic acid is discussed in ► [Chap. 149, “Folic and Folinic Acids.”](#)

Mechanism of Methotrexate-Induced Nephrotoxicity

Methotrexate is highly eliminated via the kidneys. It is a weak acid with a pH of 4.8–5.5, meaning that it is poorly soluble in an acidic environment. HD-MTX can produce renal methotrexate concentrations above its solubility, 2 $\mu\text{mol/L}$ at urine pH of 5.5. Its metabolites, 7-hydroxy-methotrexate and DAMPA, are six- to tenfold less soluble at neutral or acidic pH, respectively. 7-hydroxy-methotrexate can also compete with methotrexate on tubular secretion. Therefore, in acidic urine, methotrexate and metabolites will precipitate in the renal tubules, causing a nonoliguric, usually reversible, renal failure. Increasing the urine pH from 5 to 7 will increase methotrexate solubility by 23-fold, 7-hydroxy-methotrexate by 12, and DAMPA by 17. Maintaining an alkaline urine

(pH > 7) before, during, and after HD-MTX together with adequate hydration and urine flow can reduce the risk of methotrexate-induced renal failure and its consequences [6, 12, 16, 39, 81–86]. Renal failure significantly decreases methotrexate clearance. The resulting sustained increased plasma methotrexate concentration leads to enhanced toxicity and reduced efficacy of folinic acid.

Mechanism of Methotrexate-Induced Neurotoxicity

Methotrexate-induced neurotoxicity can be acute, subacute, or chronic and develop after systemic, intrathecal (IT), or combined administration. Both methotrexate and its polyglutamated metabolites are involved in this toxicity. Several mechanisms were proposed for methotrexate-induced neurotoxicity:

1. Inhibition of DHFR (via depletion of reduced folate)
2. Accumulation of homocysteine (toxic to vascular endothelium) and its metabolites (increased excitatory amino acids – NMDA receptor agonists)
3. Decreased synthesis of myelin sheath (due to depletion of S-adenosylmethionine and accumulation of S-adenosylhomocysteine)
4. Accumulation of adenosine (dilates cerebral blood vessels, alters release of neurotransmitters, and slows neuronal discharge)
5. Acute arachnoiditis (reported only after IT administration) [75, 76, 87]

Pharmacogenetics

All metabolic pathways of folates and methotrexate are subjected to genetic polymorphisms. This is reflected in the variable clinical response to methotrexate and its toxicity. The following include examples of genetic polymorphisms that were suggested to be associated with methotrexate toxicity [13, 20].

Methotrexate Transport

Reduced Folate Carrier Protein (RFC1)

Methotrexate is transported intracellularly via the RFC1 encoded by *SLC19A1* gene located on chromosome 21. AA homozygous patients have decreased cellular influx of methotrexate leading to high plasma concentration. In children receiving HD-MTX, the A allele was shown to be associated with liver, gastrointestinal, and skin toxicity, and the G allele with hyperbilirubinemia and vomiting. Some studies suggested that *SLC19A1* polymorphism was not associated with high plasma methotrexate concentrations. Studies in rheumatoid arthritis patients showed inconsistent results on the association between *SLC19A1* 80G > A polymorphism and methotrexate toxicity [88–94].

ATP-Binding Cassette (ABC) Transporters

P-glycoprotein (multidrug resistance protein 1; MDR1) is encoded by the *ABCB1* gene. The highly polymorphic ABC transporters mediate methotrexate efflux. *MDR1* C3435T was found to increase the risk for methotrexate toxicity. However, overall conflicting results exist on the association between single nucleotide polymorphisms (SNPs) of this gene and methotrexate toxicity [88, 95, 96].

Multidrug resistance-associated protein 1 (MRP1) is encoded by the *ABCC1*, also participating in methotrexate efflux. Several studies could not demonstrate an association with SNPs on this gene and methotrexate toxicity [95, 97].

Multidrug resistance-associated protein 2 (MRP2) is encoded by *ABCC2* gene. Some variants of *ABCC2* may affect methotrexate and 7-hydroxy-methotrexate. Data on the association with toxicity are inconsistent [95, 97]. Multidrug resistance efflux transporter ABC subfamily G member 2 (breast cancer resistance protein – BCRP) is expressed by *ABCG2* gene. This gene is involved in the transport of methotrexate and MTXpglut. Some SNPs were reported to be related to overall toxicity of methotrexate [97].

Polyglutamation of Methotrexate

Folypolyglutamate Synthetase (FPGS)

FPGS catalyzes sequential additions of glutamate residues to methotrexate, causing its intracellular retention and enhanced toxicity. SNPs on the FPGS gene encodes for polymorphisms of this enzyme. Several alleles were related to increased risk for methotrexate toxicity, especially in the presence of low activity SNPs in *gamma-glutamyl hydrolase* (*GGH*) gene [93, 98].

Gamma-Glutamyl Hydrolase (GGH)

GGH catalyzes removal of glutamic acid residues from MTXpglut, enabling efflux of methotrexate by transporters. Several SNPs in the *GGH* gene may affect polyglutamation. The presence of *GGH*-354GG was associated with myelosuppression, and *GGH*-401CC with gastrointestinal and CNS side effects in rheumatoid arthritis patients. *GGH*-401CT and TT genotypes were found to increase the risk of severe leukopenia and thrombocytopenia in children with ALL treated with HD-MTX. Other SNPs were not found to be related to methotrexate toxicity [93, 98–101].

Methotrexate-Induced Enzyme Inhibition

Dihydrofolate Reductase (DHFR)

DHFR is one of the main enzymes inhibited by methotrexate. Polymorphisms in the *DHFR* gene can be associated with an increased relapse rate in children with ALL treated with HD-MTX [102]. DHFR polymorphism was associated with hepatotoxicity in adults with ALL [103]. Conflicting results were reported on the association between *DHFR* polymorphisms and methotrexate toxicity [93, 101, 104].

Methylenetetrahydrofolate Reductase (MTHFR)

MTHFR is responsible for the conversion of $N^{5,10}$ -methylene FH₄ to N^5 -methyl FH₄, during which homocysteine is re-methylated to

methionine. Its gene, *MTHFR*, is essential for the response to methotrexate. The data on the effects of *MTHFR* polymorphisms on the activity of *MTHFR* and the response to methotrexate and its toxicity are inconsistent [88, 89, 96, 103, 105–109].

Thymidylate Synthase (TS)

TS is a major enzyme in pyrimidine synthesis. Some genetic polymorphisms in the TS gene (*TYMS*) were not associated with the response to methotrexate or with its toxicity [110].

5-Aminoimidazole-4-Carboxamide Ribonucleotide Transformylase (AICRT)

This enzyme is involved in de novo purine synthesis and is encoded by the *ATIC* gene. Polymorphisms on the *ATIC* 347G allele were shown by several studies to be associated with toxicity, e.g., gastrointestinal [107, 111, 112], but not by others.

Methionine Synthase (MS)

The conversion of homocysteine to methionine is catalyzed by MS (methyltransferase; *MTR* gene) in a process requiring B₁₂; N⁵-methyl FH₄ is converted to FH₄ at the same time. Polymorphism on the allele *MTR* 2756GG was reported to increase the risk of MTX-induced accelerated rheumatoid nodulosis [113]. Toxicity associated with other alleles has not been confirmed.

Methionine Synthase Reductase (MTRR)

MTRR activates cobalamin-dependent methionine synthase that converts homocysteine to methionine. It maintains adequate levels of methylcobalamin required for this reaction. Polymorphism of *MTRR* 66A > G allele is associated with an increased frequency of HD-MTX-induced mucositis [114].

Toxic Doses and Concentrations

Methotrexate toxicity depends on both concentration and duration of exposure. Concentrations of 0.05–0.1 µmol/L for more than 24–48 h can result

in gastrointestinal and hematological toxicity. Millimolar (mmol/L) concentrations for minutes to hours can cause renal, liver, and CNS adverse effects [20].

High-Dose Methotrexate (HD-MTX)

HD-MTX is usually defined as IV dose of >500 mg/m², range 30 mg/m² to >12 g/m². Very high doses, up to 33.6 g/m², were used together with folinic acid in childhood ALL requiring CNS preventive therapy [6, 115]. Some clinicians consider doses of 50–500 mg/m² as intermediate dose. It is generally considered that plasma methotrexate concentrations of 700 – >1,000 µmol/L and ≥1,500 µmol/L at the end of the 6-h infusion are associated with treatment success and a worse long-term outcome, respectively. Methotrexate blood concentrations measured every 24 h for 72 h after the start of the infusion are useful for detecting delayed elimination and guide dosing of folinic acid. The following plasma methotrexate concentrations define its delayed elimination and are predictive of toxicity: ≥5–10 µmol/L at 24 h, ≥1 µmol/L at 48 h, and ≥0.1 µmol/L at 48 h. These concentrations require increased dosing of folinic acid until methotrexate concentration is less than 0.05–0.1 µmol/L [6, 25]. It should be emphasized that a rise in serum creatinine of 50% and higher within 24 h after the beginning of HD-MTX (5–8 g/m²) has a sensitivity and specificity of 0.32 and 0.99, respectively, to predict delayed elimination of methotrexate [116]. A pilot matched case-control study of 11 children and 17 controls with ALL and osteosarcoma evaluated the association between plasma methotrexate concentrations and oral mucositis WHO Grade II (painful ulceration; can eat). The results showed concentrations of ≥1 µmol/L at 42 h or ≥0.2 µmol/L at 66 h after the start of HD-MTX to be associated with an odds ratio of 4.3 and 8.2, respectively, for developing oral mucositis compared with lower concentrations [117].

Low-Dose Methotrexate (LD-MTX) and Associated Medication Errors

Methotrexate oral doses of 5–25 mg/week are used to treat nonmalignant diseases (e.g., psoriasis, rheumatoid arthritis). These therapeutic doses can be associated with adverse reactions involving bone marrow, kidney, liver, intestine, skin, lungs, and mucous membranes. In general, plasma concentrations of methotrexate used for nonmalignant indications are expected to be less than 0.01 $\mu\text{mol/L}$ [17].

A retrospective study evaluated data of 28 patients aged 33–88 years admitted due to methotrexate poisoning associated with LD-MTX. Mean methotrexate dose was 10.5 ± 4.2 mg/week (range 5–20). Iatrogenic errors were made in three (10.7%) patients, daily instead of weekly dose. Seven (25%) patients died. No correlation was found between plasma methotrexate concentrations and toxicity or survival. However, it is unclear when samples were drawn relative to last dose [7].

In a series of four patients, methotrexate poisoning caused by iatrogenic errors (10–20 mg daily instead of weekly) resulted in fatalities after 5–9 days [8]. In another series of fatal iatrogenic errors, doses administered were 10 mg/day for 23 days, 20 mg/week for 3 weeks, 100 mg during 8 days, 10 mg/day for 9 days, and 15 mg/day for 6 days. Methotrexate concentrations were 0.25, 0.2, and ≤ 0.1 $\mu\text{mol/L}$, 1, 7, and 2 days after the last methotrexate dose, respectively [118]. Published cases reported survival after iatrogenic dosing errors ranging from similar doses (e.g., 60 mg weekly for 2 weeks, 2.5 mg daily for more than 6 days, 10 mg for 4 days) to much higher (i.e., 2.5 g IM) [119–122].

Unintentional Overdose

A retrospective poison center chart review identified 11 patients who unintentionally ingested methotrexate, including children; lowest age was 20 months. The most common formulation ingested was 2.5 mg tablet. Ten patients were observed at home, one at the emergency

department, all with excellent outcome [9]. No data were provided on individual dose taken, methotrexate concentrations, kidney function, and liver enzymes. Pediatric case reports described no effect or transient elevation of liver enzymes after alleged doses of 25–250 mg methotrexate. Methotrexate concentrations were 0.67 $\mu\text{mol/L}$ in one case. Folinic acid was withheld or delayed [10, 123–125]. Unintentional single oral overdose of methotrexate is usually associated with low to moderate plasma concentrations for a limited time, explaining the favorable outcome of these cases [10].

Intentional Overdose

Two self-harm attempts were reported in a retrospective poison center chart review and one pediatric. Concomitant ingestions included ibuprofen and acetaminophen. Patients were asymptomatic, without hepatic or bone marrow toxicity at 48 h post ingestion. Plasma methotrexate concentrations were 0.09 and 0.47 $\mu\text{mol/L}$, much lower than the concentration considered therapeutic [9]. The exact doses taken in these cases are unclear. Saturable intestinal absorption could limit the toxicity of acute high oral methotrexate dose.

Clinical Presentation

The toxicity profile of methotrexate varies markedly according to dose, frequency and duration of administration, route of exposure, and patient characteristics (e.g., kidney function and concomitant drugs). For example, neurotoxicity and nephrotoxicity are more common and severe in HD-MTX, whereas hematologic toxicity is more common in patients on LD-MTX who do not receive folinic acid rescue. Most of our knowledge about methotrexate toxicity comes from the adverse effects reported in HD-MTX, LD-MTX, and medication errors. The toxicity of acute overdose can be extrapolated from that knowledge.

The following is a discussion of methotrexate toxic effects according to the type of exposure:

HD-MTX, LD-MTX, medication errors, and acute overdose.

High-Dose Methotrexate

HD-MTX regimens involve the infusion of highly toxic and potentially lethal doses and require adequate patient preparation and folinic acid rescue to reduce or prevent methotrexate toxicity. Meticulous patient selection, monitoring, and intervention plan are required. In a retrospective study of patients treated with HD-MTX before 1977, there were 6% methotrexate-related deaths; 80% were attributed to severe myelosuppression resulting in either sepsis or hemorrhage and 20% to renal failure [4]. With current protocols, mortality is rare, but severe toxicity still occurs, especially in patients with delayed methotrexate clearance due to renal impairment, drug interactions, and genetic predisposition and in the elderly. The following is a discussion of the toxicity associated with HD-MTX.

Gastrointestinal: Oral mucositis occurs in up to 72% of HD-MTX treated [126–128]. It has serious consequences, including pain, route of entry for infections, and inadequate nutrition. Although mild to moderate in most cases, it may be severe in the setting of delayed methotrexate elimination and its prolonged exposure [85, 129]. Nausea, vomiting, and diarrhea can also be severe in this setting. Vomiting during the course HD-MTX infusion was one of the variables associated with high-risk plasma methotrexate concentrations and toxicity [57, 117].

Nephrotoxicity: Methotrexate administered in high doses can damage the kidneys by precipitation in renal tubules (especially if urine is acidic) or by direct toxic effect. Methotrexate-induced renal dysfunction is usually nonoliguric and reversible. It can cause delayed elimination of methotrexate resulting in sustained elevation in plasma methotrexate concentrations and increased systemic toxicity. Concurrent administration of nephrotoxic agents (e.g., IV contrast agents) and drugs interfering with methotrexate excretion (e.g., probenecid, salicylates, sulfisoxazole, penicillins, and nonsteroidal anti-

inflammatory agents) can also increase methotrexate plasma concentrations and toxicity [6, 55]. Even with current protocols of hydration, urinary alkalization and folinic acid rescue, significant morbidity and mortality due to methotrexate renal dysfunction still occur. A review of 20 clinical trials on patients with osteosarcoma between 1980 and 2002 found that the median incidence of renal toxicity was 1.5% (range, 0.0–12.4%): 1.8% developed Grade II or higher nephrotoxicity and 0.6% developed Grade III or IV nephrotoxicity. Mortality among nephrotoxic patients was 4.4%, 0.08% in all patients on HD-MTX [12]. The incidence is probably higher in patients outside clinical trials and in older patients [79]. In 48% of patients with a median age of 72 years (78% aged 50 years or older) who received HD-MTX (8 g/m²), serum creatinine doubled [130].

Hepatotoxicity: Acute transient elevation in the serum transaminases occurs in most patients treated with HD-MTX [79, 127, 128]. In a cohort of 97 osteosarcoma patients (376 HD-MTX courses, 8–12 g/m²), 81% of the patients experienced elevated ALT levels; AST and GGT were often elevated too. These enzyme abnormalities were always reversible and generally asymptomatic [128]. Increased bilirubin (less than threefold) was less frequent [127]. No reports were found on long-term hepatic complications such as fibrosis or cirrhosis.

Hematologic toxicity: Myelosuppression is a major risk of prolonged exposure to high plasma methotrexate concentrations [24]. The onset of leukopenia is between days 3 and 10 (median 6 days), with a nadir between days 5 and 15 (median 8 days). The onset of thrombocytopenia is between days 4 and 12 (median 9 days) with a nadir between days 9 and 14 (median 11 days) [131]. Infections and bleeding due to bone marrow suppression can be life-threatening [85, 129].

Neurotoxicity: Neurotoxicity may develop following IV high-dose or intrathecal (IT) administration of methotrexate. Toxicity of IT methotrexate is discussed below.

Methotrexate neurotoxicity can cause acute, subacute, and long-term effects [132, 133]; others divide it into acute and chronic [134, 135].

Acute or subacute encephalopathy generally develops within hours to days after methotrexate administration and is usually transient. Its manifestations include headache, nausea, vomiting, lethargy, fatigue, altered mental status, somnolence, confusion, blurred vision, speech disorders, ataxia, hemiparesis, choreoathetosis, seizures, and affective disturbances. The term “stroke-like syndrome” is often used to describe some of these effects [132, 133, 135].

In pediatric osteosarcoma patients, acute/subacute neurologic deficits, including hemiplegia, speech disorders, convulsions, and rapidly ascending paralysis, occurred in up to 15% of the patients. The average interval between the methotrexate course and the onset of the neurologic disturbance was 6 days (range, several hours to 20 days) [136]. Among pediatric ALL patients receiving IV and/or IT methotrexate, clinical acute/subacute encephalopathy developed in 0.8–3.8% of the patients [133–135]. The higher incidence of acute encephalopathy in osteosarcoma patients may be due to the higher doses of methotrexate used. It should be noted that acute/subacute methotrexate neurotoxicity was transient in most pediatric cancer patients. Clinical symptoms of methotrexate-induced neurotoxicity are often associated with leukoencephalopathy, evident as white matter hyperintensities on T2-weighted and fluid-attenuated inversion recovery magnetic resonance imaging (MRI) [133]. Leukoencephalopathy occurred following IV high-dose or IT methotrexate and their combination, with or without cranial irradiation. Although leukoencephalopathy is low grade in most patients, fatal diffuse necrotizing leukoencephalopathy has been reported [133, 137]. Leukoencephalopathy can also develop in asymptomatic children receiving methotrexate. In a study on 369 pediatric ALL patients treated with combined IV high-dose and IT methotrexate, 3.8% developed clinical neurotoxicity. Leukoencephalopathy was found in 20.6% of asymptomatic patients and in all symptomatic patients, persisting at the end of therapy in 74% of asymptomatic patients and 58% of symptomatic patients [133].

Chronic encephalopathy develops slowly, even months to years following HD-MTX therapy. It may progress and can permanently impair neuropsychological function. It is often associated with HD-MTX, inadequate folinic acid rescue, and prior cranial irradiation. The characteristic syndrome is leukoencephalopathy presenting with confusion, somnolence or irritability, impaired vision and speech, seizures, ataxia, and dementia; quadriparesis, coma, and death may occur [132, 134, 135]. Leukoencephalopathy involves mainly the white matter, mostly the periventricular region and the centrum semiovale. It is characterized by demyelination, multifocal white matter necrosis, astrocytosis, and axonal damage. Intracerebral calcifications, cerebral atrophy, and mineralizing microangiopathy were also reported [132]. Stabilization or partial recovery of the leukoencephalopathy was reported, mainly in children [132]. In addition, concerns were also raised about late neurocognitive effects of IT and HD-MTX [138].

Dermatologic: Dermatologic toxicity may range from mild transient erythematous eruptions to frank exfoliative dermatitis [73, 139, 140]. About 14% of patients on HD-MTX with minimal folinic acid rescue developed a patchy erythematous macular rash [141]. Alopecia, to some degree, may occur.

Ophthalmologic: Transient conjunctivitis was infrequently (4.2%) reported. It seemed not to be related to the occurrence of rash or stomatitis [73, 141] (Table 3).

Low-Dose Methotrexate

Prolonged use of low oral doses of methotrexate for systemic inflammatory diseases is considered relatively safe. However, toxicity can limit this treatment, and severe toxicity can occur under certain circumstances.

Folic or folinic acid supplementation reduces the incidence of gastrointestinal and hepatic adverse reactions. The effect on hematologic toxicity is not well defined due its low incidence [142, 143]. The following includes a discussion of LD-MTX toxicity according to organ systems.

Table 3 Main clinical manifestations of methotrexate toxicity (for the manifestations of intrathecal overdose, please see the relevant section)

	Acute methotrexate overdose	Low-dose methotrexate	Medication errors associated with low-dose methotrexate	High-dose methotrexate
Gastrointestinal	Abdominal pain, throat irritation, nausea, diarrhea	Stomatitis, nausea, vomiting, loss of appetite and weight, diarrhea, abdominal pain, dyspepsia, ulcer, bleeding	Mucositis, diarrhea	Mucositis, nausea, vomiting, diarrhea
Hematological		Myelosuppression	Pancytopenia	Myelosuppression
Neurological	Headache, dizziness/vertigo	Headache, dizziness, mood disorders, memory impairment, sleep disturbances, leukoencephalopathy (rare)		Acute and chronic encephalopathy, leukoencephalopathy
Hepatic	Minor impairment of liver enzymes	Liver enzyme elevation, hepatic fibrosis or cirrhosis	Abnormal liver enzymes	Liver enzyme abnormalities
Renal		Renal impairment (rare)		Renal failure
Lung		Interstitial pneumonitis Less frequent: noncardiogenic pulmonary edema, pleuritis, pleural effusion, progressing rheumatoid pulmonary nodules		
Dermatologic	rash	Eruptions, alopecia, photosensitivity, vasculitis, Stevens–Johnson syndrome, erythema multiforme, toxic epidermal necrolysis, exfoliative dermatitis, ulceration/necrosis	Erosive dermatitis, erythema	Erythematous macular rash progressing to bullous formation, alopecia
Cardiovascular	Chest pain, tachycardia			
Infection		Increased risk (suspected)	Pneumonia, sepsis	

Gastrointestinal: This is the most common system involved. Manifestations occur in about 30% of patients, including stomatitis, nausea, vomiting, loss of appetite and weight, diarrhea, constipation, abdominal pain, dyspepsia, ulcer, and gastrointestinal bleeding [144, 145].

Hepatotoxicity: Liver enzyme elevation is the second most common adverse effect of methotrexate [144]. A literature systematic review found a pooled cumulative incidence of 31% in methotrexate-associated liver enzyme abnormalities in the first 3 years of methotrexate use. No dose adjustment was required in most of the patients (67%); dose reduction or temporary discontinuation and to a lesser extent permanent

withdrawal of the drug were required in the rest of the patients [146]. In a meta-analysis of randomized controlled trials, methotrexate was associated with minor and major liver enzyme impairment but not with liver failure, cirrhosis, or death. The study duration (24–105 weeks) could have been too short to detect long-term methotrexate-induced severe liver toxicity [147]. Methotrexate-induced severe hepatic fibrosis or cirrhosis is uncommon but of major concern; the contribution of methotrexate as an independent risk factor has not been well established [146]. Suggested risk factors for hepatotoxicity in patients on LD-MTX include psoriatic arthritis, combination of methotrexate dose

higher than 10 mg/week and leflunomide [148], obesity, untreated hypercholesterolemia, pre-methotrexate elevated aspartate and alanine aminotransferases (AST, ALT), coadministration of a biologic agent, lack of folic acid supplementation [149], methotrexate cumulative dose higher than 3 g, alcohol use, diabetes mellitus, and hepatitis [150, 151].

Hematologic toxicity: Myelosuppression is a possible adverse effect of LD-MTX and can be associated with severe outcome. According to pooled results from 21 prospective studies, cytopenia of one cell line occurred in about 5% of the patients receiving LD-MTX up to 3 years [144]. Pancytopenia is less frequent (1.4%), and neutropenia can be associated with fatal infections [7, 152]. Elevated mean corpuscular volume (MCV) was suggested as a predictor of hematologic toxicity due to folate depletion [153].

Infections: LD-MTX was associated with increased risk of infections in some but not all studies [154, 155]. Case reports suggested an association with opportunistic infections. However, cause and effect relationship could not be established, and increased disease severity, comorbidities, and concomitant glucocorticoid use could have exposed these patients to opportunistic infections [154, 156].

Neurotoxicity: CNS toxicity is infrequent due to low penetration of methotrexate through the blood–brain barrier. It is usually mild, including headache, dizziness and mood disorders, memory impairment, and sleep disturbances [145, 157]. Nevertheless, rare cases of leukoencephalopathy have been reported [158, 159].

Nephrotoxicity: Renal insufficiency due to LD-MTX rarely occurs, if at all. Uncontrolled studies found a slight decrease in creatinine clearance in methotrexate-treated rheumatoid arthritis patients [160, 161]. Renal impairment can decrease methotrexate clearance, possibly increasing the risk of myelosuppression and other methotrexate-related toxicities. Methotrexate should be used under rigorous monitoring in patients with renal disease and avoided in patients with end-stage renal disease [162].

Pulmonary toxicity: The most frequent form of methotrexate-induced pulmonary toxicity is

interstitial pneumonitis. It has been estimated to occur in up to 50% of patients on LD-MTX, with fatality of 17%. It was suggested that the etiology is immunologic, as repletion of folate stores does not reduce its risk, but this is not proven. Clinical manifestations include dyspnea, dry cough, fever, chills, fatigue, auscultatory crackles, and hypoxemia; eosinophilia and interstitial lung opacities progressing to patchy acinar consolidation are common [163]. It may occur any time during treatment, seems to be more common in the elderly, and it is not always reversible after discontinuation of methotrexate.

Other less frequent or even rare forms of methotrexate pulmonary toxicity include noncardiogenic pulmonary edema, pleuritis, pleural effusion, and progressing rheumatoid pulmonary nodules [164, 165].

Dermatologic: Reported skin reactions include cutaneous eruptions, alopecia, photosensitivity, skin vasculitis, erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, exfoliative dermatitis, and ulceration/skin necrosis [13, 144, 151, 166]. Drug interactions and genetic predisposition may be involved in the development of severe adverse skin reactions [151].

Lymphoproliferative disorders: Methotrexate is suspected to increase the risk for lymphoproliferative diseases. Cause and effect relationship is hard to establish as rheumatoid arthritis by itself can be associated with an increased frequency of lymphoproliferative diseases [13].

Medication Errors of LD-MTX

Methotrexate toxicity can occur due to daily administration of the weekly dose or using the wrong strength tablets. Although toxicity could be mild, severe outcome was reported, even after relatively minor errors. Toxic effects reported include mucositis, pancytopenia (could be severe), diarrhea, abnormal liver enzymes, pneumonia, sepsis, multi-organ failure, and death [7, 8, 118, 119, 167, 168]. Plasma methotrexate concentrations were not different between fatal and nonfatal cases in a small retrospective study, but

these data are limited. Mortality occurred when methotrexate concentrations on admission were below 0.1 $\mu\text{mol/L}$ [7].

Acute Oral Overdose

There are few detailed reports of acute oral overdose. Most patients had favorable outcomes. The toxicity of high oral dose may be limited due to the saturable absorption and low bioavailability of methotrexate. Lack of effects or minor impairment of liver enzymes was reported in unintentional pediatric exposures treated with folinic acid [10, 124]. No effects were reported in a prospective study of 12 patients, of whom nine were adult intentional ingestions (methotrexate dose 40–1,000 mg, highest plasma methotrexate concentration 2.08 $\mu\text{mol/L}$). Some of the patients were treated with folinic acid [169]. In a retrospective poison center study evaluating 63 adult patients (88% acute overdoses, 79% unintentional), 68% were asymptomatic. The rest of the patients were mildly symptomatic, including abdominal pain, oral and throat irritation, nausea, diarrhea, headache, chest pain, tachycardia, dizziness/vertigo, and rash; 14.3% of all patients were treated with folinic acid. Hospital medical records were not available for review [170]. It is difficult to draw conclusions from these reports and series because of the limited data on dose, duration of treatment with folinic acid, and follow-up.

Diagnosis

The evaluation of patients possibly poisoned by methotrexate should include the following considerations: type and extent of overdose, clinical manifestations, risk factors, laboratory assessment (especially renal function), treatment already given, and methotrexate concentrations in relation to exposure time axis.

1. Extent of overdose: Details to be obtained include type of exposure [acute (intentional or

unintentional), subacute (e.g., medication error), chronic (LD-MTX), HD-MTX, intrathecal], cumulative dose, duration of exposure, time elapsed from last dose, and route of exposure. Folate supplementation should be assessed.

2. Clinical manifestations: Special emphasis should be given to the presence of nausea, vomiting, oral mucositis, low urine output, and myelosuppression [57, 117].
3. Identification of risk factors: Renal impairment and drug–drug interaction (e.g., benzimidazoles, nonsteroidal anti-inflammatory drugs, trimethoprim–sulfamethoxazole, other anticancer drugs, disease-modifying antirheumatic drugs). The estimated frequency of high-risk methotrexate concentrations increased from 12% to 19%, 32%, and 47% in the presence of one, two, or three risk factors (increased methotrexate AUC, low urine pH, emesis), respectively [7, 20, 57, 171, 172]. Inconclusive data exist on the association between toxicity and age, gender, and BMI [13].
4. Laboratory assessment: Mainly renal function, liver enzymes, complete blood count (neutropenia, thrombocytopenia) [117].
5. Treatment already given: This refers mainly to hydration, urinary alkalinization, and the use of folinic acid. Delay of 24–48 h in the administration of folinic acid from the beginning of HD-MTX may result in severe irreversible toxicity.
6. Determination of plasma methotrexate concentration: Methotrexate concentrations can indicate severity and guide the need and aggressiveness of hydration, urinary alkalinization, and antidotal treatment with folinic acid and glucarpidase. It is recommended to draw serial blood samples, e.g., on admission and 12, 24, 48, and 72 h after exposure. Timing can be adjusted according to the circumstances of exposure, clinical manifestations, and initial concentration. It should be noted that when plasma methotrexate concentrations are increasing or very high, the concentrations of folinic acid required for preventing toxicity (mainly myelosuppression) should be considerably higher.

Plasma methotrexate is routinely monitored by autoanalyzers using immunochemical assays. Cross-reactivity with methotrexate metabolites (mainly 7-hydroxy-methotrexate and DAMPA) can result in overestimation of the concentration. The longer the time elapsed from the administration, the higher the overestimation becomes. In addition, overestimation was higher in enzyme-multiplied immunoassay (EMIT) than in fluorescence polarization immunoassay (FPIA), compared with high-performance liquid chromatography (HPLC) reference (31% and 3% in 66-h samples, respectively) [173, 174]. Coadministration of folate and trimethoprim can diminish assay specificity [175]. It is recommended using HPLC assay after administration of glucarpidase due to the increased production of DAMPA [58, 176]. Attention should be drawn to the units expressing the results, as they may be a source of confusion (e.g., $\mu\text{mol/L}$, 10^{-7} M). We suggest using $\mu\text{mol/L}$, the most commonly used unit.

Treatment

The mainstays of treating methotrexate poisoning include supportive measures, timely gastrointestinal decontamination, adequate hydration, urinary alkalinization, antidotes (folinic acid and glucarpidase), extracorporeal elimination, and possibly gastrointestinal decontamination (Table 4). The following includes a discussion of each treatment modality.

Criteria for ICU Admission in Methotrexate Toxicity

1. Acute renal failure
2. Hemodynamic instability
3. Respiratory failure requiring ventilatory support
4. Sepsis
5. Active bleeding
6. Severe neurologic impairment (coma, seizures)
7. Intrathecal overdose

Criteria for ICU Discharge in Methotrexate Toxicity

1. Hemodynamic stability
2. No requirement for ventilatory support
3. No active bleeding
4. Resolution of sepsis
5. No further deterioration or improvement of neurologic impairment

Supportive Measures

Antiemetics, nutritional support, infection control, cardiovascular and respiratory support, and seizure control are indicated as required.

Methotrexate-induced myelosuppression should be treated using blood products, as necessary. Severe neutropenia can be treated with granulocyte colony-stimulating factor (G-CSF) such as filgrastim, sargramostim, and pegfilgrastim.

Gastrointestinal Decontamination

In patients with acute ingestion of potentially toxic or lethal dose, timely administration of activated charcoal should be considered if administered early after the overdose. Multiple-dose activated charcoal does not appear to be useful as methotrexate tablets are not known to form concretions, and there is no evidence it can increase the clearance of methotrexate [177]. One study showed smaller AUC when multiple-dose activated charcoal was given after a 6-h infusion of 1 g/m^2 methotrexate. Interruption of enterohepatic circulation was proposed as a mechanism for this observation. However, the number of patients was very small (7 treated, 8 controls), doses were separated by unusually long periods, and there is no evidence it can affect the outcome of overdosed patients [178].

There is no role for gastrointestinal decontamination in chronic overdoses (e.g., medication errors) as methotrexate is rapidly absorbed. The administration of activated charcoal has not been

Table 4 Suggested management approach of methotrexate overdose^a (for the management of intrathecal overdose, please see the relevant section)

	Acute unintentional overdose	Acute intentional overdose	Medication error associated with low-dose methotrexate	High-dose methotrexate
Gastrointestinal decontamination	Timely activated charcoal Consider gastric lavage	Timely activated charcoal Consider gastric lavage	Not relevant	Not relevant
Hydration and urine alkalinization	Usually unnecessary	Consider according to methotrexate dose and renal function Maintain adequate urine output and urine pH > 7	Begin; maintain adequate urine output and urine pH > 7 Reconsider according to dose, toxicity, and renal function Plasma methotrexate concentration has limited usefulness	Routinely performed Maintain adequate urine output and urine pH > 7 Continue until plasma methotrexate concentration < 0.01 µmol/L Note: protocols may vary; use institution protocol
Folinic acid >50 mg should be given IV; in children, consider if >25 mg	Begin with 12–15 mg/m ² every 6 h if methotrexate dose >50 mg/m ² in adults or 15 mg/m ² in children. Alternatively, use dose of folinic acid equal to the methotrexate dose. Continue until plasma methotrexate concentration < 0.01 µmol/L Reconsider according to plasma methotrexate concentration and renal function	Begin with 12–15 mg/m ² every 6 h; higher dose can be considered in large ingestion. Continue until plasma methotrexate concentration < 0.01 µmol/L Reconsider according to plasma methotrexate concentration and renal function	Begin with 12–15 mg/m ² every 6 h Consider modifying dose and interval according to cumulative methotrexate dose, duration of exposure, toxicity, and renal function Plasma methotrexate concentration has limited usefulness Continue until clinical improvement, especially bone marrow recovery	Routinely administered, e.g., 12–15 mg/m ² every 6 h beginning 24–36 h after the start of the methotrexate infusion Dose should be adjusted to methotrexate dose, scheduled plasma methotrexate concentrations, and toxicity Escalating dose should be considered according to scheduled methotrexate concentrations Continue until plasma methotrexate concentration < 0.05–0.1 µmol/L Note: protocols may vary; use institution protocol
Glucarpidase	Use has not been reported, usually unnecessary	Use has not been reported, usually unnecessary	Use has not been reported Consider according to methotrexate dose, toxicity, plasma methotrexate concentration, and renal function	FDA approved indication: plasma methotrexate concentration ≥ 1 µmol/L, and renal impairment Consider in HD-MTX-induced renal dysfunction and sustained elevated

(continued)

Table 4 (continued)

	Acute unintentional overdose	Acute intentional overdose	Medication error associated with low-dose methotrexate	High-dose methotrexate
				plasma methotrexate concentrations, e.g., >50 $\mu\text{mol/L}$ at 24 h or >5–10 $\mu\text{mol/L}$ at 42 h after start of methotrexate infusion Dose: 50 units/kg as IV bolus over 5 min. Consider second dose according to plasma methotrexate concentration
Extracorporeal elimination	Use has not been reported, usually unnecessary	Use has not been reported, usually unnecessary	Usually not required Consider according to toxicity, plasma methotrexate concentration, and renal function See HD-MTX scenario for preferred methods	Consider according to plasma methotrexate concentration, renal function, and availability of glucarpidase Most effective method: charcoal hemoperfusion and hemodialysis or high-flux hemodialysis Single most effective method: high-flux hemodialysis Note: protocols may vary; use institution protocol Caution: rebound in plasma methotrexate concentrations

^aSupportive measures: antiemetics, nutritional support, infection control, cardiovascular and respiratory support, seizure control, granulocyte colony-stimulating factor

shown to alter the outcome following methotrexate overdose.

Hydration and Urinary Alkalinization

Adequate hydration and maintaining urine output together with urinary alkalinization are essential in order to prevent renal toxicity due to methotrexate, i.e., replacement of fluid losses and avoiding tubular precipitation of methotrexate [179–181]. In a multivariate analysis, low urine

pH was one of the most important covariates of high-risk methotrexate concentrations. A more aggressive hydration and alkalinization regimen for subsequent courses reduced the frequency of high-risk methotrexate concentrations and toxicity [57].

Most HD-MTX treatment protocols recommend at least 2.5–3.5 L/m²/day of crystalloids. One protocol recommends IV infusion of 3 L/m²/day or more, in order to achieve urine output of at least 100 mL/h. When delayed elimination is suspected (vomiting, diarrhea, marked increase in

serum creatinine, or high-risk methotrexate concentration), hydration rate should be increased.

Urine pH should be maintained above 7 until methotrexate plasma concentration decreases to less than 0.1 $\mu\text{mol/L}$ (Grade II recommendation). In our institution, urine alkalinization is started by adding 50 mEq of sodium bicarbonate and 1 g (13.4 mEq) KCl to 1 l of dextrose 5%; higher concentrations may be required. Other clinicians have used higher doses such as 44–100 mEq of sodium bicarbonate in 1 l of 5% dextrose in 0.25% normal saline or 88–150 mEq in 1 l of 5% dextrose at 2–3 ml/kg/h (adults: 150–200 ml/h) [182]. Urine pH should be closely monitored, and the amount of bicarbonate modified in order to achieve the desired target of >7 . Serum pH and electrolytes, especially potassium and calcium, should be measured serially in order to avoid excessive alkalemia and electrolyte abnormalities. Hypokalemia and fluid depletion prevent effective urinary alkalinization [6, 73, 182].

In patients with osteosarcoma treated with HD-MTX, urinary alkalinization (even without forced hydration) was found to be a safe and reliable method to avoid precipitation of methotrexate and its metabolites in the renal tubules and prevented nephrotoxicity. Methotrexate dose was 8–12 g/m²; alkalinization protocol included 500 mL 8.4% sodium bicarbonate (500 mEq) over 1 h prior to HD-MTX followed by a similar dose once daily for three more days, together with KCl supplementation; target urine pH was >7.5 [86].

Drugs and Antidotes

Folinic Acid

Folinic acid (*N*⁵-formyl FH₄; Leucovorin) is the primary antidote for patients exposed to an overdose of methotrexate or to HD-MTX as part of their chemotherapy (Grade I recommendation) [183–185]. The aim of administration of folinic acid during HD-MTX treatment is to salvage normal cells and is termed Leucovorin rescue. Folinic acid rescue enables the administration of otherwise highly toxic and even lethal doses of methotrexate with an acceptable toxicity profile. The

two most important elements affecting methotrexate cytotoxicity in any tissue are drug concentration and duration of exposure. Folinic acid rescue usually begins 24–42 h and up to 48 after the start of methotrexate infusion [186, 187]. Longer delay in folinic acid administration may be associated with irreversible toxicity. In cases of delayed elimination of methotrexate, highly toxic concentrations develop even following appropriate methotrexate dosage, hydration, and alkalinization. In these cases, folinic acid doses should be intensified according to methotrexate plasma concentrations. It should be remembered that the salvage effect of folinic acid depends on both plasma methotrexate and folinic acid concentrations, but it is limited at very high methotrexate concentrations [188].

In patients with methotrexate overdose other than HD-MTX or IT regimens (i.e., acute single intentional or unintentional overdose, medication error), it is unclear when folinic acid should be administered. One approach is to promptly initiate folinic acid and reconsider it according to clinical manifestations, kidney function, blood count, and plasma methotrexate concentration [189]. This approach is based on the toxicity of methotrexate, safety of folinic acid, and its inefficacy after methotrexate-induced DNA damage has occurred.

Pharmacokinetics: Folinic acid is a racemic mixture of the active L-isomer and the inactive D-isomer. An IV preparation of the L-isomer, levofolinic acid, is also available. The bioavailability process of orally administered folinic acid is saturable and stereoselective. The absorption of the L-isomer is approximately five times higher than that of the D-isomer. The bioavailability of the L-isomer was found to be 97% at an oral dose of 25 mg and decreased to 75% and 37% at 50 mg and 100 mg doses, respectively [190]. Adult patients who require more than 50 mg folinic acid should receive the drug intravenously. After IV administration, the serum half-lives of the active L-isomer and its active metabolite *N*⁵-methyl FH₄ were 31.6 ± 1.1 min and 227 ± 20 min, respectively. The half-life of the inactive D-isomer was 451 ± 24 min [190]. The carrier-mediated transport process of

methotrexate is shared with reduced folates such as folinic acid (Fig. 3); thus, high extracellular concentrations of methotrexate can impair intracellular transport of folinic acid [188, 191].

Folinic acid is extensively metabolized intracellularly to $N^{5,10}$ -methenyl FH_4 and subsequently to N^{10} -formyl FH_4 and $N^{5,10}$ -methylene FH_4 [192].

Mechanism of action (Fig. 3): Folinic acid is a reduced, biologically active form of folic acid. It can serve as a precursor for several other reduced forms of folic acid ($N^{5,10}$ -methenyl FH_4 , N^{10} -formyl FH_4 , $N^{5,10}$ -methylene FH_4 , N^5 -methyl FH_4) that function as cofactors, providing one-carbon groups necessary for many intracellular metabolic reactions, including DNA synthesis. The mechanisms suggested for rescue of host tissue from methotrexate toxicity by folinic acid are:

1. Competitive interaction with methotrexate on their shared membrane transport carrier (reduced folate carrier – RFC), thus limiting methotrexate entry into the cell
2. Provision of reduced folate cofactors, thereby circumventing the block at the DHFR level and allowing for continued DNA synthesis
3. Direct competition of cellular folinic acid derivatives with methotrexate the level of DHFR. This promotes the net dissociation of underivatized methotrexate from DHFR (DHFR reactivation)
4. Decreased polyglutamation of methotrexate arising from competition at the level of folypolyglutamate synthetase [192–196].

The mechanism of selective rescue of normal cells but not malignant cells is incompletely understood. The two main mechanisms suggested for this selective rescue are: (1) reduced transport rate of folinic acid into transport-resistant tumor cells and (2) differential methotrexate metabolism leading to higher and sustained intracellular concentrations of methotrexate polyglutamate derivatives in tumor cells. This will result in a lesser competition of folinic acid on DHFR and its impaired reactivation [195, 197].

The protective effect of folinic acid depends on both the timing of administration and concentration of both methotrexate and folinic acid. Folinic acid must be administered before methotrexate-induced DNA damage had occurred, i.e., 24–36 h from initiating HD-MTX. In an in vitro study, toxicity of 0.1 $\mu\text{mol/L}$ methotrexate was completely reversed by equimolar concentrations of folinic acid. Higher methotrexate concentrations required relatively more folinic acid plateauing at high concentration; 10 $\mu\text{mol/L}$ but not 100 $\mu\text{mol/L}$ methotrexate was rescued by 1,000 $\mu\text{mol/L}$ folinic acid. Higher concentrations of folinic acid resulted in the formation of a precipitate in the medium [188].

Dose: The dose and duration of folinic acid should be determined according to the dose of methotrexate administered and the clinical scenario.

Mode of administration: Folinic acid can be administered orally, intravenously, or intramuscularly. Doses higher than 50 mg should be administered parenterally due to saturable absorption kinetics [198]. Some clinicians suggest that in children, doses of folinic acid higher than 25 mg be given parenterally. The infusion should be administered over 15–30 min, but not faster than 160 mg/min in adults due to its calcium content [199]. In neonates, a benzyl alcohol-free preparation should be used.

Levofolinic acid, the active L-isomer of folinic acid, is available for IV use. It should be dosed at half the dose of the racemate folinic acid.

HD-MTX regimens: Folinic acid rescue is routinely administered as part of chemotherapy regimens that include methotrexate doses of 1,000 mg/m^2 or higher. Some protocols use folinic acid in lower doses [6, 186, 200–202]. Folinic acid infusion is usually initiated within 24–36 h of the start of the methotrexate infusion. The dose and frequency of folinic acid rescue have been developed empirically and differ according to the HD-MTX regimen used [79]. The usual initial folinic acid dose is 12–15 mg/m^2 every 6 h. Serial monitoring of plasma methotrexate concentrations at 24, 48, and 72 h after the beginning of methotrexate infusion is required, and folinic acid dose is adjusted accordingly [6, 187, 198]. Other

regimens use higher initial loading dose of folinic acid and shorter intervals, especially in very high methotrexate dose, e.g., 200 mg/m² folinic acid in 33 g/m² methotrexate dose [203]. In case of delayed methotrexate elimination, folinic acid dose and duration should be increased [6]. There are several protocols for folinic acid dose escalation according to plasma methotrexate concentration following HD-MTX; two examples are presented herein:

1. Twenty-four hours after the start of the HD-MTX infusion, 10 mg folinic acid is given orally every 6 h if plasma methotrexate concentration is ≤ 10 $\mu\text{mol/L}$. If the concentrations at this time point are 10–20, 20–30, or 30–50 $\mu\text{mol/L}$, the adjusted dose of folinic acid will be 20, 30, or 50 mg orally every 6 h, respectively; concentration of ≥ 50 $\mu\text{mol/L}$ should be treated with 1 g IV folinic acid over 24 h. Concentration of ≥ 1 $\mu\text{mol/L}$ at 48 h may require further dose escalation [198]
2. Folinic acid is administered at 42 h after the start of methotrexate infusion in a dose of 30 mg/m²; at 48 and 54 h, a 15 mg/m² dose is given at each time point. If plasma methotrexate concentrations at 42 or 48 h are higher than expected (>1 and >0.4 $\mu\text{mol/L}$, respectively), folinic acid dose adjustments and methotrexate measurements are continued every 6 h, as follows: If methotrexate concentrations are >1 –2, >2 –3, >3 –4, or >4 –5 $\mu\text{mol/L}$, folinic acid dose will be 30, 45, 60, or 75 mg/m², respectively. If concentration is >5 $\mu\text{mol/L}$, folinic acid should be administered IV according to the formula: dose (mg) = plasma methotrexate concentration ($\mu\text{mol/L}$) \times body weight (kg) [202]. Folinic acid should be continued until plasma methotrexate concentration falls below 0.05–0.1 $\mu\text{mol/L}$. Overzealous dosing of folinic acid was suspected to compromise antitumor efficacy [186, 204, 205]. However, methotrexate-induced damage may not be reversible beyond 42–48 h of continuous exposure [15, 187].

Controversy exists regarding the efficacy of folinic acid in patients with methotrexate

concentrations above 100 $\mu\text{mol/L}$ [15, 188]. However, successful treatment with high-dose folinic acid (up to 10 g/day) was reported in a series of 13 patients with methotrexate concentration higher than 100 $\mu\text{mol/L}$ (range, 102–940 $\mu\text{mol/L}$) at 24 h after HD-MTX. Although all patients recovered, significant neutropenia occurred in 61%, thrombocytopenia in 53%, stomatitis in 46%, and diarrhea in 30% of them [206]. In patients with very high plasma methotrexate concentrations, addition of glucarpidase or extracorporeal elimination should be strongly considered.

Patients with ascites, gastrointestinal obstruction, or pleural effusion may require prolonged monitoring (beyond 72–96 h) and folinic acid treatment (up to weeks) because of prolonged elevated plasma methotrexate concentrations [51, 207, 208].

Medication errors of LD-MTX: Even few days of repeated low-dose methotrexate can cause severe and even fatal toxicity. These patients should be immediately treated with folinic acid and closely monitored. It should be noted that methotrexate plasma concentrations may not predict the risk, but the data for that is limited [7]. There are no evidence-based recommendations on how to adjust folinic acid dose according to plasma methotrexate concentrations in these patients. One approach is to use the same dose administered in HD-MTX chemotherapy, e.g., 12–15 mg/m² every 6 h. This dosage regimen can be modified according to the cumulative dose ingested, duration of exposure, toxicity, renal function, and perhaps plasma methotrexate concentration. It should be remembered that patients with myelosuppression might require prolonged dosing because of persistent intracellular methotrexate stores.

Acute oral overdose (intentional or unintentional): There are no evidence-based recommendations for folinic acid dose in acute oral overdose. Methotrexate toxicity may be limited due to saturable absorption and low bioavailability of large oral doses. In addition, there may be interpatient variability in tolerance to the toxic effects of methotrexate [131]. Acute single doses

of less than 50 mg/m² methotrexate in adults (single-dose regimen for ectopic pregnancy) and 15 mg/m² (range 10–25 mg/m²) in children (doses used in juvenile rheumatoid arthritis and uveitis) usually do not require folinic acid rescue. Lower thresholds can be considered in high-risk patients (i.e., renal impairment, drug interactions, and elderly patients) [209–211]. A small case series published as an abstract found no toxicity in acute oral overdose of methotrexate and suggested folinic acid can be safely withheld for ingestions of less than 500 mg in adults [169]. However, some of these patients were treated with folinic acid. One approach is to treat immediately acute oral doses of methotrexate above 50 mg/m² with folinic acid until plasma methotrexate concentrations are available.

It is usually recommended to administer folinic acid in a dose equal to the methotrexate dose [189]. Dose of 12–15 mg/m² folinic acid used in many HD-MTX cancer chemotherapy regimens should be sufficient in most cases of acute oral methotrexate exposure. Higher dose can be considered in cases of a large overdose and when delayed elimination is expected (e.g., renal impairment, drug interactions, elderly patients). We recommend monitoring plasma methotrexate concentrations within 24 h and adjusting folinic acid dose accordingly. Folinic acid should be continued until serum methotrexate concentration is below 0.01 µmol/L and preferably undetectable. In contrast with HD-MTX cancer chemotherapy, there is no “tolerable toxicity” in this case.

Folinic acid and glucarpidase interaction: Folinic acid is a substrate for glucarpidase, and they should not be administered concomitantly within 2–4 h prior or after glucarpidase. Since plasma methotrexate concentrations measured by immunoassay are not reliable during glucarpidase treatment, they cannot be used for adjusting the dose of folinic acid. The dose used prior to glucarpidase should be continued for 48 h after glucarpidase. Folinic acid should be continued thereafter according to plasma methotrexate concentrations and according to institution protocol [58, 212].

Adverse effects: Folinic acid is considered generally safe. Adverse effects include allergic or

anaphylactoid reactions. Seizures were reported in some patients who concomitantly received fluoropyrimidines and folinic acid [213].

Folinic acid should not be given intrathecally; see the section on Intrathecal Toxicity of Methotrexate.

Glucarpidase

Glucarpidase (carboxypeptidase G₂, Voraxaze) is an enzyme that rapidly metabolizes circulating methotrexate into two inactive metabolites: glutamate and 2,4-diamino-*N*¹⁰-methylpteroic acid (DAMPA). It has been used in methotrexate-induced toxicity since 1993 and gained US Food and Drug Administration (FDA) approval for treating toxic plasma methotrexate concentrations (greater than 1 µmol/L) in patients with delayed methotrexate clearance due to impaired renal function in 2012 [214].

Pharmacology and mechanism of action: Glucarpidase is a genetically engineered form of the bacterial enzyme carboxypeptidase G₂, produced by recombinant DNA technology in *Pseudomonas* species strain RS-16. It is a 390-amino acid homodimer protein with a molecular weight of 83 kDa. Each potency unit corresponds to enzymatic cleavage of 1 µmol/L of methotrexate per minute at 37 °C [212]. Glucarpidase hydrolyzes the carboxyl terminal residue of folic acid and its analogs forming inactive metabolites, glutamate and DAMPA. Glucarpidase effectively reduces plasma methotrexate concentrations; it does not penetrate intracellularly.

Pharmacokinetics: In subjects with normal renal function, the mean C_{max} was 3.1 µg/mL, mean t_{1/2} 9.0 ± 3.18 h, and mean AUC_{0–∞} 23.4 µg·h/mL. The steady-state V_d was 58 ± 18.08 mL/kg. Similar values were found in patients with severe renal impairment (creatinine clearance < 30 mL/min). In renally impaired subjects, the mean C_{max} for glucarpidase was 2.9 µg/mL, mean t_{1/2} 10.0 ± 2.06 h, and mean AUC_{0–∞} 24.5 µg·h/mL. The steady-state V_d was 67.9 ± 29.64 mL/kg [215].

Clinical efficacy: Several clinical trials studied the use of methotrexate in patients with delayed methotrexate elimination and methotrexate-induced nephrotoxicity. The criteria for delayed

elimination and nephrotoxicity were not uniform. In three studies, the median and range of methotrexate baseline concentration were 11.93 $\mu\text{mol/L}$ (range 0.52–901), 56 $\mu\text{mol/L}$ (range 1–1,187), and 28.2 $\mu\text{mol/L}$ (range 0.37–849). The mean reduction in plasma methotrexate concentration 15 min post administration was 97–98.7% [85, 129, 216]. A small rebound in methotrexate concentrations occurred in some patients [85, 216]. In a pooled analysis of efficacy data from four single-arm clinical trials from 1993 to 2007, 169 patients who had documented methotrexate plasma concentration measurement by high-performance liquid chromatography (HPLC) were studied. Rapid and sustained clinically important reduction (RSCIR) in plasma methotrexate concentration (defined as values $\leq 1 \mu\text{mol/L}$ in all post-glucarpidase determinations) was achieved in 59% of 140 patients with pre-glucarpidase methotrexate concentrations greater than 1 $\mu\text{mol/L}$. Patients who had a pre-glucarpidase methotrexate concentration of $\geq 50 \mu\text{mol/L}$ were less likely to achieve RSCIR compared with patients who had concentrations of $< 50 \mu\text{mol/L}$. However, the percent reduction of methotrexate concentrations was larger in patients with higher pre-glucarpidase methotrexate concentrations. Ninety-eight percent (44/45) of patients with pre-glucarpidase methotrexate concentrations of $\geq 50 \mu\text{mol/L}$ had 95% decrease at the first post-glucarpidase measurement, compared with 83% (92/111) of patients with pre-glucarpidase concentrations of $< 50 \mu\text{mol/L}$ [58]. In most of the cases, a second and third dose of glucarpidase did not result in an additional marked decrease in methotrexate concentration [85, 129, 216].

While glucarpidase was clearly safe and effective in reducing methotrexate concentrations within minutes of administration, it was difficult to assess its effect on renal recovery and survival due to the lack of a control group [85, 129, 216]. Varying degrees of renal dysfunction and different definitions for recovery from HD-MTX-induced renal dysfunction limit the assessment of retrospective studies comparing the efficacy of supportive treatment (including hemodialysis) and glucarpidase. In a retrospective study of

young osteosarcoma patients with HD-MTX methotrexate-induced nephrotoxicity, the median time to renal recovery was 16 days in patients on supportive care (including dialysis-based methods in some patients). In glucarpidase-treated patients, renal recovery (serum creatinine within normal values) occurred at a median of 22 days [12]. The mortality rates found in three studies on patients with delayed methotrexate elimination and methotrexate-induced nephrotoxicity treated with glucarpidase were 6.1% [85], 6% [216], and 23% [129]. One study on HD-MTX patients using multiple regression analysis model identified associations between several parameters and the development of methotrexate Grades IV and V toxicity. The parameters identified were the presence of pre-glucarpidase Grade IV nephrotoxicity, inadequate folinic acid rescue within the first 3 days after HD-MTX, diuretic use, and administration of glucarpidase more than 96 h after start of HD-MTX [216].

Safety: Glucarpidase is generally well tolerated. Main adverse events reported (about 2% of patients) include paresthesias (and related events such as burning, tingling, formication), flushing (including feeling hot, erythema), and nausea/vomiting. Less frequent adverse events (about 1%) included headache and hypotension; blurred vision, diarrhea, hypersensitivity, hypertension, rash, throat irritation/tightness, and tremor were reported in less than 1% of patients [12, 58, 212].

Anti-glucarpidase antibodies were detected in some clinical studies. In most cases it did not decrease glucarpidase activity [129, 216].

Dose and administration: Glucarpidase dose approved by the FDA for the treatment of toxic methotrexate concentration ($\geq 1 \mu\text{mol/L}$) is 50 units/kg. This dose should be administered as an IV bolus over 5 min; each vial contains 1,000 units as a lyophilized powder [58, 212]. Some studies used a second similar dose, but criteria varied, e.g., plasma methotrexate concentration of > 0.1 or $\geq 1 \mu\text{mol/L}$ more than 24 h after dose 1 and 48 h after dose 1 if pre-glucarpidase plasma methotrexate of $> 100 \mu\text{mol/L}$ [83, 129, 216]. No dose adjustment is recommended for patients with renal impairment.

The use of glucarpidase is often limited by its high cost. Glucarpidase dosages of less than 50 units/kg administered due to shortage of supply or capping the dose at a full vial size were reported to be efficacious in several cases and a retrospective study [129, 217–219]. In the retrospective study, 42% and 58% of the patients received glucarpidase doses of less than and equal or higher than 50 units/kg, respectively. The median reduction in plasma methotrexate concentrations was 99.4% in both groups (range 98–100% and 77–100%, respectively). Time to recovery of serum creatinine was not related to glucarpidase dose in multivariate analysis [219].

During glucarpidase treatment, supportive care including IV hydration, urinary alkalinization, and folinic acid rescue should be continued. Folinic acid is also a substrate for glucarpidase and can compete with methotrexate on binding to glucarpidase. Folinic acid should not be administered for 2 h before and after glucarpidase [58, 212].

Monitoring methotrexate after administration of glucarpidase: DAMPA, the inactive metabolite of methotrexate formed after glucarpidase, cross-reacts with methotrexate resulting in falsely elevated methotrexate concentrations when using immunoassays. Therefore, methotrexate concentrations should be measured during the 48 h following administration of glucarpidase only by a chromatographic method [174, 220, 221].

Current role in therapy: Glucarpidase is highly effective and safe in lowering plasma methotrexate concentration within minutes of its administration. It can decrease the need for dialysis-based methods and hence their complications. Its delayed administration, especially when cytotoxicity has already ensued, can reduce its efficacy. Glucarpidase (IV 50 units/kg) is FDA approved for treating toxic plasma methotrexate concentrations ($\geq 1 \mu\text{mol/L}$) in patients with delayed methotrexate clearance due to impaired renal function. It is suggested to consider glucarpidase in patients with HD-MTX-induced renal dysfunction (e.g., a 1.5- to 2-fold or greater increase in serum creatinine above baseline) and sustained elevated

plasma methotrexate concentrations (e.g., $>50 \mu\text{mol/L}$ at 24 h or $>5\text{--}10 \mu\text{mol/L}$ at 42–48 h after infusion) [6, 58, 222].

It should be noted that glucarpidase could handle methotrexate burden in the intravascular compartment, not intracellular or in the urinary collecting system [223].

More data are required in order to establish its efficacy in reducing severe morbidity and mortality compared with best supportive treatment, folinic acid, and elimination enhancement by dialysis-based methods.

There are no reports on the use of glucarpidase in methotrexate medication errors and intentional or unintentional overdoses.

The role of glucarpidase in intrathecal methotrexate overdose is elaborated in section “[Intrathecal Toxicity of Methotrexate](#).”

Standard supportive care, including folinic acid, must be continued following administration of glucarpidase.

Other Suggested Drugs

Dextromethorphan and aminophylline: These drugs were suggested for the treatment of methotrexate neurotoxicity. For detailed discussion, see section “[Intrathecal Toxicity of Methotrexate](#).”

Thymidine: Thymidine, an endogenous nucleoside, was used as an investigational rescue agent. It can be directly converted to thymidine monophosphate by the salvage enzyme thymidine kinase and circumvent the blockade of the de novo pyrimidine pathway by methotrexate. It was used in combination with folinic acid [81] and glucarpidase [83]. Its development was discontinued [6].

Extracorporeal Elimination

Methotrexate is a small molecule (454 kDa), about 50% protein bound, with volume of distribution of 0.4–0.9 L/kg, making it suitable though not an ideal candidate for removal by hemodialysis [224]. In a literature review on the efficacy of dialysis-based methods for removal of

methotrexate, the methods most frequently used were hemodialysis, high-flux hemodialysis, and charcoal hemoperfusion or charcoal hemofiltration [12]. Peritoneal dialysis alone resulted in a minimal decrease in methotrexate concentrations. The most effective extracorporeal removal methods were charcoal hemoperfusion in combination with hemodialysis or with high-flux hemodialysis. As a single method, high-flux hemodialysis resulted in the greatest decrease in plasma methotrexate concentrations (median 75.7%; range 42%–94%) within the shortest period of time (median 4 h; range 4–12 h) [12]. In a case series of patients with chronic and acute renal failure (three each), mean plasma clearance of methotrexate was 92.1 ± 10.3 mL/min (range 59–126.6 mL/min). One patient who was on chronic hemodialysis prior to HD-methotrexate therapy underwent 6 h of high-flux hemodialysis daily and reached a target methotrexate concentration (<0.3 $\mu\text{mol/L}$) in 5.6 ± 0.3 days, without signs of methotrexate toxicity [225]. Methotrexate dialysis clearances of 198–258 mL/min per 1.73 m² during high-flux hemodialysis were reported [226]. A major limitation of dialysis-based methods is a marked rebound in plasma methotrexate concentrations due to redistribution. Increases in post-dialysis plasma methotrexate concentrations by 10–221% of the post-procedure values and to 90–100% of the pre-procedure levels were reported [12]. This implies that prolonged course of repeated hemodialysis is required, up to 12 sessions during several days in one case report [227]. Early initiation of dialysis-based method after detection of acute exposure and before tissue distribution is completed, could be more effective in removing excess methotrexate. The time window for early removal is limited to a few hours as methotrexate distribution half-life is 0.75 h [228].

Continuous renal replacement modalities such as continuous veno-venous hemofiltration (CVVH), continuous veno-venous hemodialysis (CVVHD), and continuous veno-venous hemodiafiltration (CVVHDF) are now widely used in the management of acute kidney injury and extracellular fluid volume expansion in hemodynamically unstable patients. These techniques

are logistically easier to accomplish as they are often used in intensive care units without mobilizing experienced dialysis unit staff. However, its efficacy in treating poisoning is limited by its relatively lower clearance rate compared with hemodialysis [228]. The use of continuous renal replacement modalities to enhance elimination of methotrexate was reported in several cases [229, 230]. In one of them, several methods [CVVHD, single pass albumin dialysis (SPAD), CVVHDF, and glucarpidase] were used over 12 days in a pediatric patient who received 14.4 g for osteosarcoma and developed severe methotrexate toxicity. Methotrexate transmembrane clearance rates in this patient were 28–34.5 mL/min and 64.4 mL/min during CVVHD and CVVHDF, respectively. Compared with standard CVVHD, SPAD insignificantly increased methotrexate removal. The calculated overall amount of methotrexate removed over 97 h using these different removal methods was 2.18 g. The largest quantity of methotrexate was removed early in the course of treatment, when its plasma concentrations were the highest [229]. In another case, CVVH was used in combination with charcoal hemoperfusion. The contribution of hemoperfusion to the decline in plasma methotrexate concentrations was insignificant [231].

In clinically stable patients, frequent intermittent high-flux hemodialysis is probably the single most effective method for extracorporeal elimination of methotrexate. In unstable patients who cannot tolerate intermittent hemodialysis, continuous removal modalities can be considered. It is conceivable that high-flux hemodialysis followed by continuous removal method might achieve two goals, rapid elimination and prevention of rebound; this is yet to be proven.

Other treatments including urinary alkalization and folinic acid should be continued during extracorporeal treatments. As folinic acid is probably eliminated by extracorporeal removal techniques, supplementary doses should be given.

Glucarpidase rapidly metabolizes methotrexate to inactive metabolite (DAMPA), which may obviate the need for extracorporeal removal. Both

treatments can be combined, not simultaneously, as part of the supportive treatment of renal failure.

Intrathecal Toxicity of Methotrexate

IV and IT methotrexate are widely used for the treatment or prophylaxis of CNS involvement (leptomeningeal tumor spread) of leukemia (e.g., ALL), lymphoma, and osteosarcoma. This treatment has replaced cranial radiotherapy and substantially reduced ALL relapse [232–234]. The reasons for IT overdose of methotrexate include preparation errors such as wrong strength vial (e.g., 500 mg vial instead of 50 mg one) and administration errors (e.g., giving the higher IV dose IT) [232, 233, 235]. Contamination with other chemotherapeutic agents (e.g., vincristine) was also reported [236]. Accidental IT methotrexate overdose is rare but can be severe and fatal, depending on the dose and promptness and quality of treatment given [237].

Toxic IT Methotrexate Dose and Concentration

The clinical manifestations of IT overdose of methotrexate are usually dose dependent. They correlate with the total amount of methotrexate administered and its concentration in the CNS [238]. In some patients, toxicity can develop shortly after the first IT dose (inadvertent large overdose), and in some after few doses, even if in the therapeutic range [239]. Overlap exists between doses that were associated or not associated with neurotoxicity.

The usual IT methotrexate dose ranges between 5 and 12 mg in children [76, 239], up to 15 mg in adults [87, 233, 237], at 2–5-day intervals. Overdose of less than 100 mg or 15-fold of the therapeutic dose is believed to be relatively well tolerated, usually with treatment [240–243]. However, a 125 mg IT dose (tenfold error) in 3- and 4-year-old children resulted in generalized convulsions 3 h after administration, both completely recovered [235]. IT methotrexate overdose was defined in one study as >100 mg

[233]. A 1996 literature survey concluded that IT overdoses of <100 mg need less intervention, 100–500 mg can be treated with a variety of approaches, and >500 mg would not respond to any intervention [244]. However, some reports are in disagreement with this conclusion; survival was reported after IT overdoses of 625 mg and 1,200 mg treated with multimodalities [237, 245]. In addition, the use of IT glucarpidase can change the outcome of >500 mg IT methotrexate overdoses, as discussed later on.

IT injection of 12 mg/m² methotrexate resulted in a 100-fold variation in CSF drug concentrations. In patients treated with IT 6.25 mg or 12.5 mg/m² methotrexate, peak CSF concentrations ranged between 0.6 and 22 µmol/L. These concentrations were achieved 4–8 h after injection and decreased exponentially thereafter. Intraventricular instillations of 6.25 mg/m² via Ommaya reservoir were associated with less variability and were more reliably distributed in the CSF than after lumbar administration. Peak ventricular concentrations achieved were 200 µmol/L and declined exponentially over 48 h [246, 247].

In IT therapeutic dose (12 mg/m²), CSF methotrexate concentrations declined in a biphasic manner with half-lives of 4.5 and 14 h, approximately parallel to the plasma disappearance curve [248]. An earlier study of the same group showed that in patients treated with IT 12–15 mg/m² methotrexate, mean CSF concentrations in the neurotoxic group were 13.8 (range 1.5–100) times higher compared with the asymptomatic group. Methotrexate CSF half-life in some neurotoxic patients was similar to that found in the asymptomatic group (12–18 days) and much longer in others (48 days) [249]. In a 7-year-old boy, CSF methotrexate concentrations were 100-fold higher after an overdose of 54 times the intended dose (650 mg instead of 12 mg), and half-life doubled. The authors suggested that saturation or destruction of the transport mechanisms may have caused prolongation of the half-life [243]. CSF methotrexate concentration reached a peak of 1,250 µmol/L 9 h after an IT overdose of 1,200 mg. Plasma concentration at 7 h after the overdose was 10 µmol/L [237]. Methotrexate CSF concentration was 5.2 µmol/L at 23 h post IT overdose of

170 mg/m² (instead of 12 mg/m²) in a 2-year-old child. The only clinical manifestation was a mild headache. Methotrexate CSF elimination half-life was 8 h [241]. Earlier study found prolonged methotrexate CSF concentrations greater than 0.01 µmol/L during and after apparent neurotoxicity in patients treated with IT methotrexate [249]. It should be noted that DNA synthesis (determined as deoxyuridine incorporation into DNA) recovered to 50% of pretreatment level in mice bone marrow and intestinal epithelium only after plasma methotrexate concentration fell below 0.01 and 0.005 µmol/L, respectively [59].

Mechanisms of IT Methotrexate Toxicity

The mechanisms of methotrexate neurotoxicity are probably multifactorial; they were discussed earlier. Other mechanisms may be involved in the neurotoxicity of IT methotrexate.

Chemical preservatives, degradation products, and vehicle-induced alterations in CSF pH and osmolarity were proposed but not proven as causative [249].

The direct contact of methotrexate and its excipients with nervous tissue can be toxic and fatal due to focal tissue necrosis. This can happen after an uneventful IT injection, but also after inadvertent injection of methotrexate intraparenchymally [250, 251].

Another important factor that may play a role in methotrexate neurotoxicity after IT administration is the volume injected into the lumbar sac. The injected volume and pressure may affect distribution within the subarachnoid space and ventricular system, but this is difficult to assess. In addition, extradural and subdural leakage may occur [250].

Elevated CSF methotrexate concentrations seem to be associated with neurotoxicity after IT administration, especially in the presence of prolonged exposure. Elevated concentrations can result from high dose relative to CSF volume or impaired elimination from the CSF. Older age and the presence of meningeal leukemia were suggested to predispose to increased CSF

methotrexate concentrations and its neurotoxicity [249]. The contribution of cranial irradiation cannot be excluded.

The role of homocysteine (direct toxin to vascular endothelium) and its metabolites (excitatory amino acids, NMDA receptor agonists) should be emphasized. Hyperhomocysteinemia is a risk factor for neurodegeneration [75, 236, 252]. Elevated blood homocysteine concentrations can be associated with endothelial cell injury and cerebrovascular infarcts, explaining focal neurological deficits and seizures [250].

Adenosine also plays a role in methotrexate-induced neurotoxicity, as discussed earlier, mainly due to dilation of cerebral blood vessels, slowing release of neurotransmitters at presynaptic junctions, modifying postsynaptic response, and slowing neuronal discharge rates [253].

Several biochemical changes in the CSF were reported to be associated with IT methotrexate and HD-MTX. A study of 29 children with ALL, median age 4 years (range 2–17 years), found significantly reduced CSF concentrations of *N*⁵-methyl FH₄ and S-adenosylmethionine (SAM) in patients not receiving folinic acid rescue and in two with neurotoxicity (subacute in both). In patients, receiving rescue, CSF *N*⁵-methyl FH₄ and SAM were in the normal range. S-adenosylhomocysteine (SAH) concentrations were slightly low, but they could be quantified only in 23% of the patients [75]. This study supports other studies showing low CSF *N*⁵-methyl FH₄ and SAM in patients receiving HD-MTX or intraventricular methotrexate together with elevated homocysteine [254, 255] and in a rodent model [256]. Low CSF SAM was reported to be associated with demyelination in patients with leukoencephalopathy [257, 258]. High CSF adenosine concentrations were found in patients treated with methotrexate compared with control subjects, when toxicity was absent or mild [259].

Clinical Manifestations of IT Methotrexate Toxicity

Neurotoxicity after IT methotrexate is more common and severe than after IV or oral

administration [76]. Leukoencephalopathy was reported in 40% and less than 10% of patients treated with IT and IV methotrexate, respectively [87].

Methotrexate-induced neurotoxicity can be manifested in three main forms: acute, subacute, and chronic. Following therapeutic IT administration, these three forms are characterized by the following:

1. Acute chemical arachnoiditis including headache, back pain, confusion, nausea, vomiting, dizziness, nuchal rigidity, fever, and seizures; usually reversible but can be fatal
2. Ascending myelopathy manifested with leg pain, sensory alterations, neurogenic bladder, intestinal ileus, stroke-like episodes (e.g., hemiparesis, dysphasia, stupor); usually reversible, can be severe
3. Leukoencephalopathy usually manifested by confusion, irritability, tremor, ataxia, progressive personality changes, dementia, focal neurological signs, and seizures can be irreversible and fatal. Combined IV and IT methotrexate and cranial irradiation put the patient at a greater risk for delayed chronic leukoencephalopathy [16, 75, 76, 243, 249, 250].

A retrospective study of 18 pediatric patients, mostly with ALL, 17 received only IT methotrexate, reported the following clinical manifestations: headache, slurred speech, dizziness, disorientation, confusion, agitation, weakness, ataxia, numbness, dysarthria, aphasia, dysphagia, behavioral disorders, somnolence, mental status changes, impaired sensorium hemiparesis, incontinence, and convulsions. These manifestations appeared 2–12 days after last methotrexate dose, thus considered as subacute toxicity [76]. In another study on accidental IT methotrexate overdose, five of seven patients developed acute severe toxicity within 1 h after the overdose. Clinical manifestations included seizures, coma, apnea, hypotension, tachycardia, hypertension, confusion, severe headache, intense back pain, nausea, and vomiting [233]. Case reports supported these findings [87, 237, 239, 260, 261]. Adult respiratory distress syndrome (ARDS) was reported in one case [237].

Intraparenchymal injection can result in acute elevation in intracranial pressure, massive brain edema, cystic defect, monoparesis, and permanent neurological deficit [250, 251].

Ancillary Tests

Electroencephalogram (EEG): A tenfold IT methotrexate error was associated with a disturbed background rhythm shown as a slow activation increase and paroxysmal activation in the right temporal region [232]. An EEG done in a 22-year-old patient with behavioral and speech disturbances after a cumulative IT methotrexate dose of 62.5 mg showed excessive bilateral slow-wave activity suggestive of diffuse cerebral dysfunctions [260].

Magnetic resonance imaging: White matter changes can be found in MRI imaging before overt clinical neurotoxicity, reflecting demyelination, necrosis, and angiopathy [250]. MRI findings after IT methotrexate with subacute toxicity included ischemic lesions in the white matter characterized as supraventricular infarcts and demyelination [75]. In one patient, serial MRIs with diffusion-weighted imaging showed recurrent areas of restricted diffusion within cerebral hemispheric white matter, which correlated chronologically with the IT administration of methotrexate and severity of the clinical manifestations [239]. In another case, diffuse symmetric bilateral hyperintense T2 signal abnormality within the white matter was reported [87].

Some studies suggest that up to 40% of patients may develop MRI or CT changes indicative of methotrexate-induced leukoencephalopathy, although clinical neurotoxicity may not be seen [87].

Management of IT Methotrexate Overdose and Toxicity

There is limited data on IT methotrexate overdose and no well-established guidelines for treating this medical emergency. It is emphasized that prompt recognition of the overdose and immediate

adequate multimodality treatment are critical to improve short- and long-term outcomes. Treatment strategies of IT methotrexate overdose and toxicity include removal of CSF fluid with or without exchange, systemic folinic acid, systemic and IT corticosteroids (preferably dexamethasone), IT glucarpidase, and combined treatments [232, 233, 237, 262]. The use of aminophylline and dextromethorphan was also suggested.

CSF drainage/exchange: This treatment modality was reported in a series of patients and several cases, including asymptomatic high-dose incidents. Lumbar puncture is used for this purpose; ventriculolumbar perfusion should be considered in continued or worsening neurotoxicity [233]. In a series of seven pediatric and adult patients receiving an IT overdose of 155–600 mg (median 364 mg) methotrexate, four underwent CSF exchange, mainly with warm saline. This procedure removed 32–58% of the dose. The patients also received IT glucarpidase after the exchange and IV folinic acid and dexamethasone [233]. Lumbar CSF exchange was performed in a 34-year-old male after an inadvertent administration of 1,200 mg methotrexate IT. The procedure lasted 48 h during which 200 mL of CSF were exchanged with warm normal saline. Methotrexate CSF concentrations decreased from 1,250 to 47 $\mu\text{mol/L}$. At the end of the exchange, 2 mg folinic acid and 2 mg dexamethasone were injected IT. The patient was also treated with IV folinic acid for 72 h and IV mannitol to reduce intracranial pressure [237]. Removing IT methotrexate using lumbar drainage is expected to be successful if done within a short time after injection, as it reaches the basal cisterns within an hour. In large overdoses and late recognition of the error, ventriculolumbar perfusion should be considered [263, 264]. A 6-year-old boy received 600 mg IT methotrexate instead of the intended 12 mg dose and rapidly developed severe acute neurotoxicity. He was successfully treated with rapid lumbar CSF drainage of 15 mL CSF 2 h after the overdose followed by ventriculolumbar perfusion with 240 mL warmed normal saline. Within 8.5 h of administration, 90% of the drug was removed. IT 2,000 U glucarpidase was also

administered; the patient fully recovered [265]. The use of IT glucarpidase after lumbar CSF drainage while administering systemic corticosteroids and folinic acid may preclude the need for ventriculolumbar perfusion [233, 266]. Future studies may indicate whether IT glucarpidase may obviate the need for ventriculolumbar perfusion [262].

Technical considerations of CSF drainage/exchange:

- (a) CSF drainage. This is done using lumbar puncture. CSF volume reported to be removed is 10–70 mL [244, 262, 264–266]. According to a pharmacokinetic model, early CSF drainage is predicted to remove larger doses of methotrexate, and smaller volumes can be used. For example, drainage of 20–40 mL CSF within 15, 30, and 60 min will remove 94%, 72–89%, and 40–79% of the injected methotrexate dose, respectively; larger volume will remove a greater dose. Ten mL CSF drained at these time points will result in removal of 54%, 36%, and 20% of IT injected methotrexate dose, respectively [264]. Therefore, remove larger CSF volumes if longer time has elapsed from the IT overdose. The first CSF fluid removed is usually yellow, becoming clearer later on [232].
- (b) CSF exchange. CSF is exchanged with warm normal saline via a lumbar or ventricular catheter. Exchanged volumes via lumbar catheter reported were 20 mL, total volume of 210–250 mL [242]; 3 mL every 15 min, total volume 72 mL [232]; 200 mL over 48 h [237]; and 240 mL over 2 h [266]. Volumes exchanged via ventricular exchange were 80–250 mL during 3 h [266]. Ventricular exchange requires the presence of a neurosurgeon.
- (c) Ventriculolumbar perfusion. This is done by ventriculostomy and lumbar drainage and depends on the availability of neurosurgeons. One study suggested using this procedure in >10-fold overdose, unless large volume of CSF can be removed by lumbar drainage within 15 min of the overdose [266]. Another study suggested it in overdose of >100 mg

or >7-fold the intended dose [264]. Preservative-free warm normal saline is administered through the ventriculostomy, and an equal amount of CSF is removed through the lumbar side. Volumes used were 130 mL over 1.5 h and 240–250 mL over 3–4 h [265, 266].

Corticosteroids: Dexamethasone is the preferred corticosteroid due to its better penetrance of the blood–brain barrier; it can be given IV, IT, or by both routes. Pediatric IV dexamethasone dose reported was 0.15 mg/kg every 6 h, four doses [232].

The IV dose of dexamethasone used in most reports is 4 mg every 4–6 h. The reported range was 0.15 mg/kg to 4 mg/m² and up to 20 mg/m²/day in three divided doses. Duration of treatment ranged between 1 and 3 days; longer treatments were also reported [232, 233, 235, 261, 262, 264, 265].

IT dexamethasone was administered in a case of a large IT methotrexate overdose (1,200 mg). Five 2 mg doses of dexamethasone were given IT during lumbar CSF exchange, and an additional one at the end, together with IT 2 mg folinic acid. Although the patient recovered from the overdose, it is unclear what were the contributions of IT dexamethasone and folinic acid. The rationales for the IT dexamethasone in this case were persistent elevated CSF methotrexate concentration (47 μ mol/L), relieving arachnoiditis and preventing adhesions [237].

Folinic acid: Folinic acid should be given only IV, not IT because of increased risk for seizures and death [244].

The dose used in one case series was 100 mg every 6 h, four doses [233]. However, a broad range of doses were used: 12 mg every 12 h, 15 mg/kg every 3–6 h, 30 mg/kg every 6 h, 100 mg every 3 h, 40 mg/m² every 6 h (in children), 100 mg/m² every 3 h, and 200 mg/m² every 3 h. Some reports also used a loading dose of 1,000–1,200 mg [232, 235, 237, 244, 261, 262, 264, 265]. Duration of treatment ranged between 12 h and several days. The use of lower doses of folinic acid may be considered in smaller overdose (e.g., 50 mg every 3–6 h in < 100 mg methotrexate overdose).

Another report used IV 1,200 mg folinic acid followed by 15 mg every 6 h for 72 days, concomitantly with lumbar CSF exchange. In this report, 2 mg folinic acid were also administered IT after the exchange; no neurotoxic adverse effects of folinic acid were recorded. Its role in the recovery from the overdose is unclear [237].

In a pediatric case, 300 mg (instead of 12 mg) IT methotrexate was followed by headache, coma, and seizures after 90 min. Treatment included 100 mg IV levogyrum folinic acid (equivalent to double dose of the racemic mixture of folinic acid) every 3 h for 24 h and then every 6 h for 24 more hours. The patient regained consciousness and remained in normal neurological status [261].

An 11-year-old boy was treated with three doses of IT 50 mg folinic acid each over 24 h after an IT 20 mg methotrexate overdose (a dose not expected to be lethal or to cause severe neurotoxicity). Shortly after completion of the folinic acid treatment, he developed seizures and fatal multi-organ failure [244]. Folinic acid was found to be associated with seizures in cancer patients [213].

If glucarpidase is administered IT, it is suggested to continue folinic acid for at least 48 h after it. Glucarpidase hydrolyzes folinic acid, and the continued administration can ensure adequate repletion of reduced folate stores [262].

Glucarpidase: In an animal study using nontoxic and toxic doses of IT methotrexate, IT glucarpidase caused a dramatic and very rapid decrease in methotrexate CSF concentrations; all animals survived without neurotoxicity [267]. IT glucarpidase was administered to seven pediatric and adult patients with accidental overdose of IT methotrexate (median dose 364 mg). Four of them received it after CSF exchange. Median CSF methotrexate concentrations before IT glucarpidase were 264 μ mol/L and 8,050 μ mol/L in patients who underwent prior CSF exchange and those who did not, respectively. Glucarpidase was given via either lumbar, ventriculostomy, Ommaya reservoir, and lumbar and ventriculostomy routes, at a median of 5 h (range 3–9 h) after the IT overdose. Following this treatment, CSF methotrexate concentrations decreased by more than 98% within 2 h. Five patients fully

recovered, and two were left with memory impairment. IT glucarpidase was well tolerated; no antibodies to glucarpidase were detected. It should be noted that these patients also received IV folinic acid and dexamethasone. The authors of this study concluded that although the contribution of glucarpidase to the favorable outcome of the patients cannot be precisely determined, the rapidity in which it decreased CSF methotrexate concentrations and its lack of toxicity suggest it is beneficial in this form of overdose [233]. A single dose of 2,000 U IT glucarpidase was administered after CSF lumbar drainage and ventriculolumbar perfusion to a 6-year-old boy with IT methotrexate overdose (600 mg instead of 12 mg). It resulted in a further 150-fold decrease in CSF methotrexate concentration; the patient fully recovered [265]. A literature review concluded that IT glucarpidase caused a nearly 2-log reduction in CSF methotrexate concentrations in patients receiving 155–600 mg methotrexate IT; neurologic outcome was excellent.

The usual IT glucarpidase dose is 2,000 U reconstituted in 12 mL normal saline and administered over 5 min [233, 262, 265].

Dextromethorphan: Dextromethorphan is the methylated D-isomer of levorphanol, acting centrally in the medulla oblongata to suppress cough. Unlike the L-isomer, it has little analgesic and minimal addictive properties. It is a noncompetitive NMDA receptor antagonist [268]. Its use was reported in a retrospective study of 18 children (mean age 11.2 years) with subacute methotrexate toxicity; 16 received it IT as a 12 mg dose. Dextromethorphan dose ranged between 1 and 3 mg/kg/bid to 2.5 mg/kg/qd for 1–20 days; 12 (66.6%) patients were treated for 4 days. Symptomatic improvement was noted in all of patients within 0.2–43 h and 15 (83.3%) within 12 h. Time to resolution after initial onset ranged between 2 h and 20 days, 13 (72.2%) within 7 days, two (11.1%) had long-term sequelae (ataxia, left-sided weakness) [76]. Although this study is a retrospective non-placebo-controlled one, its results suggest dextromethorphan be considered for the treatment of methotrexate neurotoxicity, especially after IT administration.

Aminophylline: Aminophylline, a methylxanthine competitive adenosine antagonist, was suggested to be used in methotrexate neurotoxicity. According to one case series, 2.5 mg/kg IV aminophylline as a 45–60 min infusion reversed subacute neurotoxicity after HD-MTX in four out of six pediatric patients (3–16 years old). Response was observed after or during the infusion. These patients received IV methotrexate, not IT [259]. A later publication reported on a 20-year-old patient treated with 15 mg IT methotrexate together with other chemotherapeutic agents who developed rapid consciousness deterioration, diminished verbal output, and behavioral changes. She was treated with 145 mg aminophylline daily for 7 days together with IV folinic acid, with gradual cognitive and behavioral improvement over the next 6 months [87]. A 16-year-old patient with subacute neurotoxicity after 12 mg IT methotrexate was treated with 5 mg/kg aminophylline every 6 h and folinic acid. He improved clinically and radiologically over 7–10 days. However, neurotoxicity recurred after re-administration of IT methotrexate, in spite of prophylactic aminophylline and folinic acid [239]. The contribution of aminophylline to the recovery is unclear. Although aminophylline use was not reported after IT methotrexate, biologic plausibility and some beneficial effects reported suggest it may be used also in severe or large IT methotrexate overdose.

Suggested Treatment Recommendations for IT Methotrexate Overdose

No controlled studies evaluated the efficacy and safety of the available treatments of IT methotrexate overdose, and no well-established guidelines exist. The following suggested approach relies on case series, case reports, and approaches recommended by other clinicians; it should not be considered evidence based.

Early recognition of the overdose and the prompt use of multimodality treatments are the two main principles critical for reducing short- and long-term outcomes and death.

1. *Prevention.* This is certainly the best treatment modality; attention should be drawn to the dose

prescribed for IT administration, dose prepared, and route of administration (IT instead of IV). It is suggested to keep the methotrexate vials used and review the whole process of drug administration, before and immediately after the IT injection.

2. *Supportive treatment.* This includes hydration and maintaining adequate urine output, urinary alkalization, and seizure control.
3. *Clinical evaluation.* Determine time elapsed from IT injection; assess clinical manifestations of neurotoxicity, severity, and time to onset; obtain kidney function tests, plasma, and if possible also CSF methotrexate concentrations; consider EEG, CT, or MRI.
4. *Determination of the dose administered.* Three dose ranges were reported according to severity of neurotoxicity and outcome: less than 100 mg, 100–500 mg, and higher than 500 mg.
5. *Principles of treatment according to the methotrexate dose injected IT:*

- (a) *<100 mg dose.* Immediate CSF drainage, IV folinic acid (15–50 mg), and dexamethasone (2–4 mg in adults, 0.15 mg/kg in children), every 6 h, four doses of each; continue according to clinical manifestations.
- (b) *100–500 mg dose.* Immediate CSF drainage and exchange (lumbar, ventricular if delayed diagnosis). Consider ventriculolumbar perfusion if high methotrexate dose or prolonged time elapsed from the IT overdose (e.g., several hours) due to the rapid distribution of methotrexate throughout the CSF. Administer IV folinic acid (40 mg/m² or 100 mg), and dexamethasone (4 mg in adults, 0.15 mg/kg in children), every 6 h, four doses of each; continue according to clinical manifestations. Consider IT 2 mg dexamethasone and IT 2,000 U glucarpidase after the drainage/exchange/perfusion.
- (c) *>500 mg dose.* Immediate CSF drainage and exchange. Urgently proceed to ventriculolumbar perfusion, IV folinic acid (40 mg/m² or 100 mg), and dexamethasone (4 mg in adults, 0.15 mg/kg in

children), every 6 h, four doses of each; continue according to clinical manifestations. Administer IT 2,000 U glucarpidase after the drainage/exchange/perfusion, and consider IT injection of 2 mg dexamethasone. Consider dextromethorphan (1–3 mg/kg/bid for 4 days) and IV aminophylline (2.5 mg/kg daily for up to 7 days).

- (d) *Monitoring CSF methotrexate concentrations.* CSF methotrexate concentrations 24 h after IT glucarpidase administered for IT overdose were $\leq 0.65 \mu\text{mol/L}$, similar to the concentrations found after therapeutic dose of IT methotrexate [233]. This may be considered as a desired target concentration, until which treatments should be continued. Methotrexate is hydrolyzed in the CSF to DAMPA which cross-reacts with methotrexate in immunoassays. It can result in falsely elevated concentration of methotrexate, and an HPLC assay is preferred in these circumstances [233, 262].

Reproductive Toxicity and Lactation

Methotrexate is an abortifacient. A 50 mg/m² dose is used for a nonsurgical termination of ectopic pregnancy. It is also a human teratogen, causing a characteristic pattern of malformations including (but not limited to) the skull, limb, other skeletal, and craniofacial and growth restriction, termed methotrexate embryopathy. Adverse pregnancy outcomes seem to be dose and gestational time dependent. A critical period for exposure of 6–8 weeks after fertilization and a critical dose of 10 mg/week were suggested based on a limited number of observations [269]. However, other small studies reported on malformations after exposure in earlier stage of pregnancy [270] and lower doses (7.5 mg) [271]. Most cases of congenital defects were observed after a failed attempt of pregnancy termination [272]. The teratogenic potential of methotrexate in dosage

typically used for the treatment of rheumatoid arthritis remains uncertain. There are reports on healthy babies born after exposure to LD-MTX during the first few weeks of gestation, before pregnancy was diagnosed [273]. A prospective cohort study found that postconception exposure to LD-MTX (≤ 30 mg/week) was associated with a higher rate of spontaneous abortions (42.5%; adjusted hazard ratio 2.1, 95% CI 1.2–3.2 using disease-matched controls) and major birth defects (6.6%; statistically higher than 2.9% in healthy controls, insignificant from 3.6% in the disease-matched controls). Preconception exposures were not different from the control group. None of the malformations were clearly consistent with methotrexate embryopathy [274].

Male reproduction: The effect of methotrexate on male fertility is not well determined. Azospermia or oligospermia was documented in patients after HD-MTX, but since the chemotherapy regimens included other drugs and sometimes radiotherapy, it is difficult to determine the role of methotrexate. Chronic LD-MTX was reported to have no effect in several case reports and studies and reversible sterility by others [275]. Paternal LD-MTX was not found to be associated with adverse pregnancy outcome in an observational cohort study of 113 pregnancies [276].

Lactation: Data from a case report suggest low levels in breast milk following a daily 15 mg/m² oral dose for choriocarcinoma, milk plasma ratio of 0.08 [277]. The author of another case report believes that parenteral weekly doses of methotrexate can be used in lactating women with active rheumatoid arthritis [278]. This approach is not widely accepted. Breastfeeding during HD-MTX is contraindicated.

According to an international panel of rheumatologists, methotrexate should not be used by women and men for at least 3 months before planned pregnancy and should not be used during pregnancy or breastfeeding [279]. According to the manufacturer, pregnancy should be avoided during and for a minimum of 3 months after therapy for male patients and during and for at least one ovulatory cycle after therapy for female patients [33].

Body Surface Area Calculation

Calculating body surface area (BSA) is required for determining methotrexate and folinic acid doses. Several formulas exist for this purpose; Mosteller formula is a common and simple one:

$$BSA (m^2) = \sqrt{\frac{\text{height (cm)} \times \text{weight (kg)}}{3600}} \quad [280].$$
 Online calculators and nomograms (e.g., West nomogram [281]) can be easily found on the Web.

Key Points in Methotrexate Toxicity

1. Methotrexate is used to treat a variety of malignant and nonmalignant illnesses.
2. Methotrexate poisoning can occur in the following settings: high dose for cancer chemotherapy, low-dose and its associated medication errors, acute overdose (intentional/unintentional), and intrathecal overdose.
3. Medication errors associated with low-dose or intrathecal methotrexate can be severe and even fatal.
4. Toxicity includes myelosuppression, renal impairment, gastrointestinal disturbances (e.g., mucositis), and hepatic enzyme abnormalities.
5. Treatment principles: hydration, urine alkalization, folinic acid, glucarpidase, and extracorporeal elimination.
6. Folinic acid must be administered before methotrexate-induced DNA damage had occurred; delay may be associated with irreversible toxicity.
7. Glucarpidase should be used in severe toxicity determined by plasma methotrexate concentrations and renal function.
8. In medication error of LD-MTX and acute overdose, folinic acid should be initiated as soon as possible, before obtaining plasma methotrexate concentration.
9. Intrathecal overdose requires prompt identification, CSF drainage/exchange or ventriculolumbar perfusion, and systemic folinic acid and dexamethasone; intrathecal glucarpidase can be used in severe overdose.
10. Methotrexate is a known human teratogen.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are a chemically diverse class of compounds that share anti-inflammatory, analgesic, and antipyretic properties. Both therapeutic and adverse effects of NSAIDs are primarily due to cyclooxygenase (COX) inhibition. There are different types of COX, denoted as COX-1, COX-2, and COX-3 (which is considered a variant of COX-1) [1].

NSAIDs are commonly utilized and comprise up to 2.5% of all prescription dollars spent, globally. A National Health Interview Survey in 2010 revealed that 12.8% of adults in the United States were taking NSAIDs at least three times a week for 3 months, which represented a more than 40% increase in use since 2005. Further, telephone surveys reveal that 26% of users of over-the-counter NSAIDs take more than the recommended dose [2]. These factors explain the finding that adverse effects from NSAIDs are among the most common drug side effects reported in the United States and worldwide [3]. In 2005, the US Food and Drug Administration released a statement stressing “the importance of using the lowest effective dose for the shortest duration possible if treatment with a NSAID is warranted for an individual patient” [2]. This thought is echoed throughout current literature.

Despite the significant number of reports of toxicity from chronic use and overuse, intentional acute overdosage of NSAIDs is rarely life-threatening and death from acute NSAID overdose is quite rare.

The author would like to thank Anthony “Tony” Morkunas who contributed to the first edition of this chapter.

Biochemistry and Clinical Pharmacology

Metabolism of phospholipids by the enzyme phospholipase A₂ produces arachidonic acid, a 20 carbon unsaturated fatty acid which is embedded in cellular membranes. During inflammatory processes, arachidonic acid is converted into prostaglandins and thromboxanes. This conversion is mediated by COX, lipoxygenase, and cytochrome P450 enzymes. Nonsteroidal anti-inflammatory drugs prevent the substrate arachidonic acid from binding to the active site of COX enzymes (Fig. 1).

Pathophysiology of Toxic Effects

In general, the COX-1 isoform performs house-keeping functions, such as gastric mucosal protection. Due to its function in maintaining homeostasis, COX-1 is found in high concentrations in many cells and tissues, including endothelial cells, platelets, renal collecting tubules, and the gastrointestinal (GI) tract. Conversely, COX-2 is inducible by mediators of inflammation, such as tumor necrosis factor and cytokines. Nonsteroidal anti-inflammatory drugs can downregulate COX-2 pathways, thereby inhibiting inflammation. These differences in COX isoenzymes has led to classifying various NSAIDs by strength of inhibition of each isoenzyme, with nonselective NSAIDs inhibiting both COX-1 and COX-2 enzymes and selective NSAIDs inhibiting COX-2 more than COX-1 enzyme. Despite these classifications, both COX-1 and COX-2 are expressed in many tissues and there is overlap in COX-1 and COX-2 function. For instance, COX-2 derived prostaglandins play a role in maintenance of GI mucosal integrity and COX-1 derived prostaglandins contribute to inflammation [1, 4–7]. Further, we are discovering that there is significant similarity in the clinical toxicity produced by nonselective and selective NSAIDs. It appears that dose may be more important than laboratory-defined COX selectivity. At higher doses, COX selectivity blurs [1].

While some continue to classify by COX selectivity (“nonselective” if the NSAID inhibits both COX-1 and COX-2 well and “selective” if it

primarily inhibits COX-2; selective is also sometimes denoted as COXIB), others prefer to classify NSAIDs by chemical composition (See Tables 1 and 2). Most reviews include both classifications and both can be useful clinically; however, NSAIDs classified as selective do not always share common adverse effect profiles with each other, even at therapeutic doses. For instance, regardless of selectivity, GI side effects may occur with most NSAIDs, particularly in the lower GI tract [1]. The same is true for adverse cardiovascular effects, especially at high doses [1]. Some propose that solubility and partition coefficients, pH, and pKa may determine the distribution of various NSAIDs into various body tissues, contributing to differing toxic effects from different NSAIDs. Table 3 lists pharmacokinetic parameters of some NSAIDs. Others have suggested that NSAIDs target Ca⁺⁺ induced K⁺ channels but differ in their ability to affect the channels and produce toxicity [1]. Still others suggest that differential transport of NSAIDs with transporters such as the organic anion transporting polypeptide 2A1 (OATP2A1) may account for varying toxicity of various NSAIDs [1].

Clinical Presentation and Life-Threatening Complications

Adverse effects and clinical toxicity may occur from: drug-drug interactions (Table 4), acute allergic reactions, chronic use and overuse, and acute overdosage. While the focus of this textbook is acute overdose and associated toxicity, drug-drug interactions and chronic toxicity are so common with NSAIDs due to the prevalence of their use that these adverse effects are discussed. Allergic reactions are less common, but can be life-threatening, and are also discussed.

Acute Allergic Reactions

Nonsteroidal anti-inflammatory drug hypersensitivity reactions have been reported with diclofenac, ibuprofen, naproxen, ketoprofen, phenylbutazone, and oxyphenbutazone [17].

Fig. 1 Actions of NSAIDs. In normally functioning cells, phospholipase converts phospholipids in the cell membrane into arachidonic acid, which begins the arachidonic acid cascade. Arachidonic acid is further converted to PGG₂ by COX enzymes. PGG₂ is then converted to PGH₂ by peroxidase. Under normal circumstances, the action of COX enzymes on arachidonic acid eventually produce prostaglandins D₂, E₂, F_{2α} (PGD₂, PGE₂, PGF₂), prostacyclins (PGI₂), and thromboxane A₂ (TXA₂), needed for gastrointestinal mucosal protection, maintenance of renal perfusion, and regulation of platelet aggregation. NSAIDs

limit the production of PGG₂ by inhibiting COX enzymes, which subsequently results in less PGH₂. Since NSAIDs reduce the amount of PGH₂ that can be acted upon by cell specific synthases to produce prostaglandins (PGD₂, PGE₂, PGF₂), prostacyclins (PGI₂), and thromboxanes (TXA₂), many cell functions are altered. The reduced production of prostaglandins, prostacyclins, and thromboxanes can affect vasoconstriction/vasodilation, platelet aggregation, neuroprotection, neurodestruction (e.g., apoptosis), inflammatory responses, and carcinogenesis

Acetaminophen and salicylates, which are discussed in other chapters, have also been associated with hypersensitivity reactions. Nonsteroidal anti-inflammatory drugs are amongst the most likely drugs to induce anaphylaxis. Single oral administration of a NSAID may result in anaphylaxis. Nonsteroidal anti-inflammatory drug-induced anaphylaxis is likely due to an IgE-mediated response, may occur rapidly, and may be life-threatening [17–19]. Retrospective analysis of an allergy service in the Netherlands found that 17% of hospitalizations were related to NSAID hypersensitivity, 30% of which were secondary to diclofenac. The most common reaction was anaphylaxis, in this hospitalized group [18]. Of note, nonallergic drug hypersensitivities, commonly called pseudoallergic or idiosyncratic reactions, may result from NSAID use as well.

Topical NSAID application, such as topical ketoprofen use, may produce contact and photocontact allergic reactions as well as anaphylaxis [17, 19].

Adverse Effects and Clinical Toxicity Due to Chronic Use

Generally, higher doses, longer duration of use, and comorbidities of the patient are associated with increased risk of adverse drug effects from NSAIDs. Additionally, genetic susceptibility may contribute to variable toxicity. The major adverse effects of NSAIDs involve the GI, renal, and cardiovascular systems; however, other systems may also be affected [1]. These adverse effects will be discussed systematically.

Table 1 Classification by chemical structure^a

Chemical class	Examples of drugs: generic name (brand name)
Acetic acids	Bromfenac (Duract[®]) – a benzene acetic acid; withdrawn from US market due to severe hepatotoxicity, resulting in death and transplantation [8–10] Diclofenac (Voltaren[®], Cataflam[®]) – a phenylacetic acid; associated with DILI [10] Etodolac (Lodine[®], Lodine XL[®]) – an indole acetic acid Indomethacin (Indocin[®]) – an indole acetic acid Sulindac (Clinoril[®]) – an indene acetic acid Tolmetin (Tolectin[®]) – a heteroaryl acetic acid
Butanones (Ketones)	Nabumetone (Relafen[®]) – a prodrug
Diarylheterocyclics (also, COXIBs or COX-2 selective inhibitors)	Rofecoxib (Vioxx[®]) – a furanone; a sulfone; withdrawn from US and other markets due to risk of myocardial and cerebral infarctions Celecoxib (Celebrex[®]) – a sulfonamide derivative; a pyrazole; occasional DILI [10] Valdecoxib (Bextra[®]) – a isoxazole; a sulfonamide derivative; withdrawn from US and other markets Paracoxib (Dynastat[®]) – injectable prodrug of valdecoxib; not on US market Etoricoxib (Arcoxia[®]) – a bipyridine; a sulfone; not on US market Lumiracoxib (Prexige[®]) – a phenylacetic acid; never on US market; analog of diclofenac; highly COX-2 sensitive; associated with liver toxicity (severe hepatic necrosis, requiring transplantation or resulting in death) [9–12]
Fenamic acids (anthranilic acids)	Meclofenamic acid (Meclomen[®]) Mefenamic acid (Ponstel[®])
Oxicams (enolic acids)	Meloxicam (Mobic[®]) Piroxicam (Feldene[®])
Propionic acid derivatives	Fenoprofen (Nalfon[®]) Flurbiprofen (Ansaid[®]) Ibuprofen (Motrin[®]) – occasional DILI [10] Ketoprofen (Orudis[®]) Naproxen (Naprosyn[®]) Oxaprozin (Daypro[®]) Suprofen (Suprol[®]) – off US and other markets
Pyrazolones	Oxyphenbutazone Phenylbutazone
Pyrrolo-pyrroles	Ketorolac (Toradol[®]) – a carboxylic acid; banned from many European markets; significant gastrointestinal toxicity
Salicylates (discussed in a separate chapter)	Acetyl salicylic acid (Aspirin[®]) Sulfasalazine (Azulfidine[®]) Diflusal (Dolobid[®])
Sulphonanilides	Nimesulide (never on US market; severe hepatotoxicity) [10]

Key: *DILI* drug-induced liver injury, *US* United States, *COX* cyclooxygenase

^aThis table is a composite of many works [1, 4, 10, 13]. Of note, there is some variation in classification by chemical structure amongst different authors. The brand names given are examples of those used in the United States. These may differ in other countries

Neurological and Neurovascular Effects from Chronic Exposure

Cerebrovascular accidents: There is controversy regarding the risk of stroke with NSAID use [1, 15]. Studies are historical and contradictory. For instance, one retrospective cohort study revealed an increased risk of stroke among users of rofecoxib and valdecoxib but not diclofenac, ibuprofen, naproxen, and indomethacin; however, another retrospective cohort study revealed both

nonselective (naproxen, indomethacin, piroxicam, meloxicam, diclofenac) and selective (celecoxib and rofecoxib) NSAIDs were associated with increased risk of stroke. In the later study, ibuprofen was the only NSAID that did not increase the risk of stroke [1]. Most clinical trials suggest an association of increased thromboembolic events with NSAID use, regardless of COX-2 selectivity. In general, meloxicam appears to present less risk than rofecoxib and celecoxib

Table 2 Classification by COX-1 and COX-2 isoform selectivity^a

COX 1 selective (Low COX-2 inhibition: COX-1 inhibition ratios; lowest listed at top)	Unselective (Progressing from more COX 1 selective to more COX-2 selective)	COX 2 selective ^b (High COX-2 inhibition: COX-1 inhibition ratios; highest listed at top)
Ketorolac ^c	Meclofenamate	Etodolac
Flurbiprofen	Sulindac	Celecoxib
Ketoprofen	Naproxen	Meloxicam
Indomethacin	Piroxicam	
Tolmetin	Ibuprofen	
Aspirin (Acetylsalicylic acid)	Acetaminophen	
Nabumetone	Sodium salicylate	
Fenoprofen	Diffunisal	

This table was generated from multiple sources [1, 4, 5, 13]

Key: COX cyclooxygenase

^aNote: COX 1 selective and unselective are generally called “nonselective” and COX 2 selective is generally referred to as “selective” or “COXIB”

^bOthers that are typically classified as COX-2 selective but that are not available on the US market include: rofecoxib (thrombotic disease), nimesulide (liver toxicity), valdecoxib (thrombotic disease), lumiracoxib (liver toxicity), etoricoxib, and paracoxib

^cOff the market in France, Germany, and some other countries for bleeding complications, primarily perioperatively, and for renal failure, especially in the elderly or those with impaired renal function. Ketorolac has a higher relative risk of GI bleeding than most NSAIDs

Table 3 Pharmacokinetics of some NSAIDs^a

NSAID	Bioavailability (%)	Half-life (h) (therapeutic; may differ in overdose) ^b	Volume of distribution (L/kg, unless otherwise stated)	Clearance (L/h; unless otherwise stated)	Primarily renally eliminated (Y/N)	Peak (h) (therapeutic; may differ in overdose)	Protein binding (%)
Celecoxib	Solution: 64–88 Capsule: 22–40	6–12	400 L	27.7	N (hepatic metabolism; inhibits CYP2D6)	2–4	97
Diclofenac	50–60 (first-pass effect)	1–2	0.1–0.2	21.0	Y	2–3	99
Ibuprofen	>80	2–4	0.15	3–3.5	Y	0.5	99
Ketoprofen	90	2	0.1	6.9	Y	1–2	99
Meloxicam	89	15–20	10 L	0.4–0.5	half	4–10	99
Naproxen	95	12–17	0.16	0.13 ml/min/kg	Y	1	99

Many sources were used to develop this table [7, 13, 14]

^aGenerally, most NSAIDs are acidic, have high bioavailability, and are highly protein bound. Most are metabolized by the liver. Some (such as, naproxen, ibuprofen, and ketoprofen) are also glucuronidated by renal enzymes [1]

^bWhile NSAIDs (excluding Aspirin) reversibly inhibit the COX enzyme, drugs with long half-lives, such as piroxicam with its half-life of 30–86 h, will appear to irreversibly inhibit COX enzyme. Further, in overdose half-lives of all NSAIDs may be prolonged. Aspirin irreversibly inhibits COX enzyme; thus, new COX enzyme must be made to restore function

and most studies indicate that ibuprofen does not present a significant stroke risk [1].

Aseptic meningitis: Aseptic meningitis generally presents with fever, headache, photophobia, and meningeal signs (e.g., neck stiffness). Less

commonly, confusion, lethargy, and seizures are seen. Aseptic meningitis is a rare complication of NSAID use, but NSAIDs are the most common cause of drug-induced aseptic meningitis. Aseptic meningitis has been reported following

Table 4 Drug-drug interactions producing toxicity and critical illness

Drug or drug class that interacts with NSAIDs	Effect	Some specific interactions
Angiotensin-converting enzyme inhibitors ^a	Increase risk of renal compromise, hyperkalemia, and hypertension	Indomethacin (and probably other NSAIDs) inhibits the antihypertensive response of captopril; however, sulindac has a small opposing effect of the antihypertensive efficacy of captopril and enalapril
Angiotensin inhibitors	Increased risk of renal compromise and hyperkalemia	
Anticoagulants	GI side effects (e.g., bleeding)	NSAIDs can produce hypoprothrombinemia, but the effect is variable and dependent on the specific NSAID COX-2 selective agents can have platelet-aggregating effects and compete with warfarin for albumin binding sites NSAIDs increase the incidence of bleeding in patients receiving heparin therapy
Antidiabetic agents (Sulfonylureas and insulin)	Increased risk of hypoglycemia	Phenylbutazone enhances the hypoglycemic response of antidiabetic agents
Beta-blockers	Increased risk of hypertension	NSAIDs (indomethacin, flurbiprofen, piroxicam) reduce the antihypertensive effects of beta-blockers Sulindac is less likely to interfere with beta-blockers Calcium channel blockers have lesser interactions with NSAIDs than do beta-blockers
Corticosteroids	GI side effects (e.g., ulceration, bleeding)	
Cyclosporine	Increased risk of cyclosporine toxicity (nephrotoxicity)	Sulindac increased cyclosporine concentrations and serum creatinine (2- to 3-fold) within 3 days Indomethacin increases nephrotoxicity in animals Mefenamic acid increases serum creatinine and cyclosporine concentrations within 1 day
Diuretics	Increased risk of renal compromise and hypertension	Concomitant administration of indomethacin, diclofenac, or ibuprofen with triamterene has produced hyperkalemia Indomethacin may inhibit the formation of prostaglandins, which protect against drug-induced nephrotoxicity
Ethanol	Increased risk of GI bleeding	A two- to threefold increase in incidence of minor gastric bleeding has been reported with co-ingestion of ethanol and NSAIDs
Hydralazine	Increased risk of hypertension	Indomethacin increases blood pressure through inhibition of prostaglandin synthesis
Lithium	Increased risk of lithium toxicity	NSAIDs (including COXIBs) increase serum lithium levels to varying degrees (12–448%), depending on the NSAID Elevations in lithium levels may occur in as few as 3 days Diclofenac, ibuprofen, indomethacin, ketorolac, mefenamic acid, naproxen, phenylbutazone, and piroxicam reportedly interfere with renal prostaglandins that are involved in the excretion of lithium

(continued)

Table 4 (continued)

Drug or drug class that interacts with NSAIDs	Effect	Some specific interactions
Methotrexate	Increased risk of methotrexate toxicity (hematologic toxicity)	NSAIDs may increase methotrexate levels Toxicity is generally seen at higher (antineoplastic) doses of methotrexate and less commonly with lower doses Diclofenac prior to high-dose methotrexate therapy has resulted in serious methotrexate toxicity Flurbiprofen, co-administered with low-dose methotrexate, has reportedly produced neutropenia, thrombocytopenia, and GI bleeding Ibuprofen decreases the renal clearance of methotrexate by 50% and doubles the methotrexate area under the curve Death has occurred with concomitant use of indomethacin, ketoprofen, naproxen, and phenylbutazone
Serotonin reuptake inhibitors (SSRIs)	Increase adverse GI effects (e.g., GIB)	SSRIs increase bleeding risk by inhibiting platelet adhesion and function Conversely, tricyclic antidepressants do not appear to increase GI risks as much

This table was generated from many sources [1, 4, 15, 16]

Key: *GIB* gastrointestinal bleed, *COXIBs* COX-2 selective

^aIncreases in blood pressure with NSAIDs are most pronounced when co-administered with angiotensin II receptor blockers (ARBs) and angiotensin-converting-enzyme inhibitors (ACEIs) and lowest with calcium channel blockers and loop diuretics [16]

therapeutic doses of ibuprofen, naproxen, sulindac, piroxicam, diclofenac, ketoprofen, and tolmetin. It occurs most commonly in women with systemic lupus erythematosus. The cause may be direct chemical irritation of the meninges by the NSAID but may also involve a hypersensitivity reaction. Laboratory findings include pleocytosis, primarily neutrophils, in the CSF, with associated elevations of protein; however, the cultures will be negative for infectious agents [20–22]. The differential diagnosis should include medication overuse headache, a refractory, chronic headache that resolves following cessation of the NSAID.

Hearing loss: Transient and persistent sensorineural hearing loss have been reported to occur after therapeutic doses of ketorolac [23, 24].

Pulmonary Effects from Chronic Exposure

Asthma: There is nearly complete cross-reactivity between aspirin-induced asthma and nonselective NSAID-induced asthma. Selective NSAIDs do not often appear to exacerbate asthma, although

there are a few case reports of cross-reactivity with aspirin-induced asthma [15, 16, 18]. Patients with nasal polyps, a marker of arachidonic acid metabolism abnormalities, are more likely to experience NSAID-exacerbated respiratory disease. Genetic susceptibility contributes to this risk [18].

Cardiovascular Effects from Chronic Exposure

Myocardial infarction: Once it was discovered that rofecoxib increased the risk of serious cardiovascular events (e.g., myocardial infarctions, congestive heart failure, and cardiac failure events), the cardiovascular risks of other NSAIDs were investigated. Meta-analyses revealed that other NSAIDs are associated with adverse cardiovascular events, such as myocardial infarction. This risk appears to be dose dependent, but some agents are more strongly associated with cardiovascular events. Low-dose ibuprofen has cardioprotective effects, similar to aspirin; however, high-dose ibuprofen increases cardiovascular risks [1, 15]. Diclofenac use presents a 40–60% higher relative risk of serious

cardiovascular events, compared to no NSAID use. This risk appears to be at least equivalent to rofecoxib, which has been withdrawn from the US market [1, 6, 15]. Despite this, diclofenac is the most commonly used NSAID worldwide [1]. Etoricoxib, which is not available in the United States, also appears to increase the risk of adverse cardiovascular events. Conversely, celecoxib and etodolac (both selective NSAIDs), and naproxen (a nonselective NSAID), have very low risks of adverse cardiovascular events [1, 6]. Patient factors, such as previous myocardial infarction, contribute to the risk of myocardial infarction, especially when taking higher doses of NSAIDs [1].

Dysrhythmias: Multiple studies indicate an increased risk of atrial fibrillation associated with NSAID use, especially long-term use [1].

Gastrointestinal Effects from Chronic Exposure

Dose- and duration-dependent adverse effects range from mild (dyspepsia, nausea) to severe (duodenal ulcers, gastrointestinal bleeding and stricture of the lumen, occasionally complicated by obstruction and perforation) [2]. In general, the most severe adverse effects involve the distal (lower) GI tract, while the more mild effects are more proximal (upper GI tract). Patients taking NSAIDs have a relative risk of 4.7 for upper GI bleeding and perforation, compared with nonusers; however, this risk varies depending on the agent [2] (See Table 5). Enteric-coated and sustained release products may decrease upper GI symptoms; however, these preparations increase the risk of distal GI toxicity, which is more serious [1].

Some measures can be taken to limit the GI toxicity induced by NSAIDs. Patient risk factors, such as advanced age; previous GI injury; and concurrent therapy with anticoagulants, aspirin,

corticosteroids, and selective serotonin reuptake inhibitors (SSRIs) also contribute to toxicity; therefore, other agents should be considered [2]. When topical, rather than oral, NSAIDs can be utilized, this should be done to limit the GI side effects [1]. Protective strategies, such as the co-administration of misoprostol, are recommended to limit GI toxicity (Grade I evidence) [2]. Modeling suggests that a proton pump inhibitor may reduce upper GI adverse effects [15]. Meta-analysis of nine randomized clinical trials comparing celecoxib with nonselective NSAIDs found less GI side effects associated with celecoxib [1]. However, this data cannot be extrapolated to other selective NSAIDs, as rofecoxib does not appear to provide this advantage [1].

Hepatic Effects from Chronic Exposure

NSAIDs (when acetaminophen is included) are third, following antibiotics and anticonvulsants, as causes of drug-induced liver injury (DILI) [10]. Up to 10% of cases of DILI are felt to be attributable to NSAIDs and nearly all NSAIDs have been implicated in causing liver injury [9, 12] (Table 6). A higher incidence of DILI has been described with diclofenac and sulindac compared to other NSAIDs. Most DILI caused by NSAIDs is minor; rarely, severe hepatotoxicity develops, occasionally resulting in death or the need for liver transplantation [10]. Nonsteroidal anti-inflammatory drug-induced liver diseases include: acute hepatitis, cholestasis (ibuprofen), cholestatic hepatitis (sulindac), chronic hepatitis (diclofenac), granulomatous hepatitis (phenylbutazone), and acute liver failure (bromfenac, lumiracoxib; neither are on US market) [12].

A genetic predisposition to DILI has been noted with diclofenac and lumiracoxib (not on US market) [10]. Lumiracoxib is structurally similar to diclofenac. The hepatotoxicity is generally idiosyncratic [10]. However, nongenetic risk factors are involved in NSAID-induced DILI as well, including use of other hepatotoxic drugs and chronic liver disease [10]. The hepatotoxicity of both diclofenac and lumiracoxib can be delayed for 1–3 months and has been associated with hepatotoxic metabolites and glutathione adduct

Table 5 Relative risk of GI bleeding with NSAIDs [7]

Low risk:	Ibuprofen (RR = 2.23)
Moderate risk:	Diclofenac (RR = 3.61)
	Naproxen (RR = 4.46)
	Indomethacin (RR = 5.12)
High risk:	Ketorolac (RR = 14.54)

RR Relative risk

Table 6 NSAID-induced liver injury

NSAID	Type of liver injury seen	% of reported NSAID-induced hepatotoxicity ^b
Diclofenac	Hepatocellular injury	34.1%
Ibuprofen ^a	Hepatocellular injury (some cases may occur with hepatitis C) Cholestasis Vanishing bile duct syndrome	14.6%
Sulindac	Cholestatic Hepatocellular injury Mixed pattern Generalized hypersensitivity reactions (associated with most of the fatal cases)	12.4%
Naproxen	Hepatocellular injury Cholestasis Rarely, immune-allergic hypersensitivity reactions Cross-hepatotoxicity with fenoprofen	11.1%
Piroxicam	Cholestatic jaundice Hepatocellular injury Rarely, hypersensitivity (rash, fever, eosinophilia)	9.3%

Note: While this table is unique, much of the data is derived from the text, graphs, and tables found in the article by Unzueta A, et al. [10]

^aIbuprofen has one of the best hepatotoxic safety profiles of the NSAIDs; however, because it is one of the most frequently used NSAIDs, it is responsible for a significant number of cases

^bAcetylsalicylic acid is responsible for 12% of reported NSAID-induced hepatotoxicity; acetaminophen-induced hepatotoxicity was not included in the data used to populate this table

formation, with glutathione depletion, oxidative stress, and mitochondrial injury [12, 25]. With lumiracoxib use, severe hepatocellular necrosis associated with positive auto-antibodies (antinuclear antibodies) has resulted in the need for transplantation and in death [9, 12].

Renal Effects from Chronic Exposure

Kidney injury: It is estimated that 2.5 million people in the United States experience NSAID-mediated renal disease annually [5]. Acute and chronic renal failure, with an associated reduction in glomerular perfusion and filtration rate, are seen [1]. Understanding blood flow to the kidney helps elucidate this disease process (See Fig. 2). Prostaglandins normally dilate the afferent arteriole bringing blood to the glomerulus. Nonsteroidal anti-inflammatory drugs limit prostaglandin production, producing vasoconstriction of the afferent arteriole, thereby limiting blood flow to the glomerulus [1, 26].

Risk factors for NSAID-mediated renal disease include: high doses, concomitant use of medications that alter renal autoregulation, age greater than 65 years, male gender, intravascular volume depletion, cardiovascular disease, diabetes, and pre-existing chronic renal disease [1, 5, 15]. Nonsteroidal anti-inflammatory drugs may produce renal papillary necrosis, acute interstitial nephritis (AIN), and the nephrotic syndrome. Renal papillary necrosis may result from medullary ischemic injury [1, 5]. The nephrotic syndrome is characteristic, with edema, oliguria, foamy urine, hematuria, and proteinuria. Acute interstitial nephritis is generally reversible [1, 5, 26]. Chronic renal failure (CRF) secondary to NSAIDs is rare but may occur secondary to interstitial nephritis or papillary necrosis [1]. While regular doses of NSAIDs are unlikely to produce CRF, high doses of NSAIDs increase the risk significantly [1].

Electrolyte abnormalities: Generally, all NSAIDs are associated with sodium retention, edema, and weight gain, regardless of COX selectivity. Hyponatremia is the most common electrolyte abnormality seen with NSAID use. Hyperkalemia, likely secondary to potassium retention, also occurs, regardless of COX selectivity; however, hypokalemia may also occur [1, 5, 27]. Hypocalcemia, hypomagnesemia, and hypophosphatemia are also reported [27]. Renal tubular acidosis, type 4, with associated electrolyte abnormalities may be seen [5].

Hypertension: Hypertension may worsen in previously hypertensive patients once placed on NSAIDs. In one study, rofecoxib was associated

Fig. 2 NSAID effects on the kidney. The afferent arteriole normally dilates in response to prostaglandins; this results in an increased GFR. NSAIDs inhibit this effect by reducing the production of prostaglandins. This produces relative vasoconstriction of the afferent arteriole and decreases GFR. Conversely, angiotensin II normally constricts the efferent arteriole to increase GFR. However, ACE inhibitors inhibit this effect and produce a relative dilation of the efferent arteriole; this decreases GFR.

Administration of ARBs also leads to vasodilation of the efferent system. By acting at different sites to reduce GFR, NSAIDs (afferent vasoconstriction) and ACE inhibitors/ARBs (efferent vasodilation) can significantly limit GFR when administered concomitantly. This explains the increased risk of renal insufficiency and failure seen when these agents are used together [5]. *GFR* glomerular filtration rate, *ACE* angiotensin-converting-enzyme, *ARBs* angiotensin II receptor blockers

with worsening hypertension, while celecoxib was associated with a lower risk, revealing that this adverse effect is independent of COX selectivity, although this is not uniformly found in all studies [1]. The mean increase in systolic blood pressure is 2–3 mmHg, but it can be much greater, especially if the patient is co-ingesting angiotensin converting enzyme inhibitors, angiotensin II receptor blockers, beta-blockers, or diuretics [15]. This effect has been demonstrated in randomized controlled trials.

Immunologic Effects from Chronic Exposure

NSAIDs (with acetylsalicylic acid included) are the most frequent drugs involved in hypersensitivity drug reactions. Hypersensitivity may be mediated by immunoglobulin E (IgE), by T cells, or by activation of pathways that release vasoactive mediators (histamine, prostaglandins, sulfidopeptide leukotrienes) [17, 18]. Immunologic disease includes NSAID-induced respiratory disease (e.g., anaphylaxis, which is discussed above),

cutaneous disease (e.g., delayed fixed drug eruptions, Stevens-Johnson syndrome, toxic epidermal necrolysis), renal disease (e.g., nephritis, which is discussed above), and hepatic disease (which is discussed above) [9, 17, 18]. A multisystem hypersensitivity syndrome characterized by fever, rash, hepatic injury, and lymphadenopathy has been reported as well [28].

Both nonselective and selective (e.g., valdecoxib) NSAIDs may produce serious skin reactions [12]. The most frequent dermal reactions are exanthemas that are maculopapular and are commonly due to ibuprofen or naproxen. Contact dermatitis and photosensitivity may occur, generally triggered by ketoprofen and diclofenac. Severe reactions such as toxic epidermal necrolysis or Stevens-Johnson syndrome have been only rarely reported with NSAID use; these syndromes can prove fatal [15, 17, 18]. Chronic propionic acid-NSAID use has also produced pseudoporphyria, with bullous photosensitivity and similarities to porphyria cutanea tarda [29].

Hematopoietic Effects from Chronic Exposure

Phenylbutazone can produce serious blood dyscrasias, including aplastic anemia, agranulocytosis, and thrombocytopenia [30]. Phenylbutazone is sometimes referred to as “bute” and has been taken illicitly by jockeys and other racetrack workers [30]. Oxyphenbutazone, a metabolite of phenylbutazone, can produce similar toxicity.

Adverse Effects and Clinical Toxicity Due to Acute Overdosage

NSAIDs are generally well tolerated in overdose, with acute poisonings most commonly producing minimal morbidity and very rarely death. However, large overdosage may produce toxic encephalopathy, seizures, respiratory failure, cardiovascular arrest, renal failure, and hepatic injury. In the United States, ibuprofen is one of the most frequently ingested NSAIDs in acute overdose. Several deaths have been reported [27]. Lodise et al. report of a 51-year-old man who presented after intentional, isolated ibuprofen ingestion, confirmed by gas chromatography/mass spectrometry (GC/MS). The patient presented with coma, hypotension, metabolic acidosis, and respiratory depression. Despite vigorous supportive care, he died 4 h after arrival to the ED. Postmortem examination revealed edema of the brain, heart, and lungs, with unspecified myocardial injury. Postmortem ibuprofen concentrations were approximately 25 times greater than therapeutic concentrations [27]. Naproxen is also commonly ingested. Al-Abri et al. report of a 28-year-old man who ingested 70 g of naproxen and ethanol. He was drowsy, tachycardic, and developed metabolic acidosis that was treated with continuous venovenous hemofiltration (CVVH). He had recurrent seizures and respiratory failure requiring intubation. His naproxen concentration was approximately 40 times greater than therapeutic concentrations [31].

While many NSAIDs share a similar clinical appearance in overdose, there are notable distinctions. Clinical findings of acute NSAID overdoses found in the literature are summarized in Table 7,

and the unique features of different classes of agents are further delineated in the footnotes of Table 7 and in the discussion that follows.

Some important points to remember when caring for patients with large overdoses of NSAIDs, reviewed by system, include:

Neurologic: Acute psychosis and auditory hallucinations have been reported with overdosage of indomethacin, diclofenac, sulindac, and mefenamic acid [4]. Seizures, including status epilepticus, may occur, especially after overdosage of mefenamic acid [4, 32]. A retrospective review of single-agent exposures resulting in seizures from 1997 to 2010 in Switzerland revealed that mefenamic acid was the most prevalent cause of drug-induced seizures; however, due to its current infrequent use, this is not likely the case now [45]. Nystagmus, diplopia, miosis, and blurred vision have also been reported following overdosage of NSAIDs [4, 32]. The pupils may be fixed in miosis, but this should not be utilized as a prognosticator, since patients with this finding have made full neurological recoveries [56].

Pulmonary: Pulmonary edema and respiratory distress syndrome (ARDS) in conjunction with multiple organ failure have occurred in overdose [4, 50].

Renal: A profound, anion-gap, metabolic acidosis can occur with massive overdoses, occasionally with pH less than 7 [48, 49].

Complications of overdosage: Complications of toxic encephalopathy and hypotension may occur and occasionally prove fatal. These can include: aspiration pneumonia, respiratory failure, rhabdomyolysis, ischemia, and sepsis [27, 56, 61]. Rarely, dysrhythmias, such as ventricular fibrillation, and cardiac arrest have been reported [27]. Ischemic necrosis of the extremities may ensue [36].

Diagnosis of Acute Overdose

Blood studies: Symptomatic patients warrant the following basic blood studies: complete blood count, electrolytes, renal function tests, and liver

Table 7 Reported clinical findings with acute NSAID overdose^a

NSAID	Clinical findings in overdose
General NSAID overdose [4, 32–35]	<p><i>Neurological</i>: headache, dizziness, toxic encephalopathy (irritability, agitation, or coma), seizures, blurred vision</p> <p><i>HEENT</i>: tinnitus</p> <p><i>Pulmonary</i>: hyperventilation, respiratory alkalosis (rarely respiratory failure)</p> <p><i>Cardiovascular</i>: mild hypotension and tachycardia (rarely cardiovascular collapse or dysrhythmias)</p> <p><i>Gastrointestinal</i>: GI distress (nausea, vomiting, diarrhea, abdominal pain), rarely GI bleeding, rarely pancreatitis</p> <p><i>Hepatic</i>: hepatic injury, generally mild</p> <p><i>Renal</i>: sodium and water retention, rarely acute renal failure, hematuria, proteinuria</p> <p><i>Heme</i>: hypoprothrombinemia (prolonged prothrombin time), rarely: neutropenia, aplastic anemia, agranulocytosis, leukocytosis, thrombocytopenia</p>
Acetic acids (diclofenac, etodolac, indomethacin, sulindac) [33, 36–40]	<p><i>Neurological</i>: headache, dizziness, toxic encephalopathy (disorientation, irritability, agitation, hallucinations, coma), quadriplegia with interspersed choreiform movements (rare), extensor reflexes on plantar stimulation (rare), fixed gaze (without doll's eye movements; rare)</p> <p><i>HEENT</i>: tinnitus</p> <p><i>Pulmonary</i>: respiratory arrest (rare)</p> <p><i>GI</i>: GI distress (vomiting, abdominal pain); colonic perforation (with diclofenac; rare)</p> <p><i>Hepatic</i>: falsely elevated bilirubin (due to the phenolic metabolites of etodolac); hyperbilirubinemia (with normal liver enzymes in patient with sulindac overdose)</p> <p><i>Renal</i>: acute kidney injury, proteinuria, hematuria, renal failure (anuria)</p> <p><i>Hematopoietic</i>: hypoprothrombinemia, bone marrow aplasia and cytopenias, granulocytosis (transient, with acute sulindac overdose)</p> <p><i>Integument</i>: skin necrosis (ischemic)</p>
Diarythetereocyclics (celecoxib) [41]	<p><i>Neurological</i>: drowsiness, irritability, agitation</p> <p><i>GI</i>: GI distress, abdominal pain</p> <p><i>Integument</i>: rash</p>
Fenamic acids (flufenamic acid, meclofenamic acid, mefenamic acid, tolfenamic acid) [26, 32, 42–45]	<p><i>Neurological</i>: toxic encephalopathy (agitation, coma) seizures,^b dyskinesia, muscle twitching, hyperreflexia, extensor plantar response, miosis</p> <p><i>Cardiovascular</i>: cardiopulmonary arrest (rare)</p> <p><i>GI</i>: GI distress (vomiting, diarrhea)</p> <p><i>Renal</i>: acute renal failure</p> <p><i>Hematopoietic</i>: hypoprothrombinemia</p>
Propionic acid derivatives^c (fenoprofen, flurbiprofen, ibuprofen, ketoprofen, naproxen, oxaprozin) [27, 31–33, 46–60]	<p><i>Neurological</i>: dizziness, headache, drowsiness, toxic encephalopathy (agitation, coma), seizures (rare; may be recurrent), muscle twitching (rare), nystagmus (rare), diplopia (rare), blurred vision, miosis, unreactive pupils (rare; with eventual full neurological recovery), ataxia, vertigo</p> <p><i>HEENT</i>: tinnitus, decreased hearing</p> <p><i>Pulmonary</i>: hyperventilation (respiratory alkalosis with metabolic acidosis; generally, less severe than is seen with salicylate), respiratory depression (rarely, respiratory arrest)</p> <p><i>Cardiovascular</i>: tachycardia, bradycardia (rare), hypotension, congestive heart failure (rare), dysrhythmias (rare), cardiac arrest (ventricular tachycardia/fibrillation; very rare)</p> <p><i>GI</i>: GI distress (nausea, vomiting, abdominal pain, hematemesis); pancreatitis (rare)</p> <p><i>Hepatic</i>: liver failure (very rare); hyperbilirubinemia^d</p> <p><i>Renal</i>: hematuria and proteinuria; polyuria; acute renal insufficiency; acute renal failure (tubular necrosis, nephritic syndrome); metabolic acidosis (common, though generally mild; however, may be severe in large overdosage); hyperkalemia; hypokalemia; hyponatremia; hyponatremia</p> <p><i>Hematopoietic</i>: hypoprothrombinemia, thrombocytopenia</p> <p><i>Metabolic/endocrine</i>: hypothermia (rare, but more often than hyperthermia);^e adrenal insufficiency</p>

(continued)

Table 7 (continued)

NSAID	Clinical findings in overdose
Pyrazolones (oxyphenbutazone, ^f phenylbutazone ^f) [30, 33, 61]	<i>Neurological</i> : toxic encephalopathy (irritability, agitation, coma), seizures (may include status epilepticus) <i>Cardiovascular</i> : tachycardia, hypotension, cardiovascular collapse <i>Pulmonary</i> : respiratory depression and failure, respiratory alkalosis, pulmonary edema <i>GI</i> : GI irritation, ulceration and GIB <i>Hepatic</i> : hepatic injury (hepatocellular, cholestasis) <i>Renal</i> : hematuria, acute renal failure (may require weeks of hemodialysis), electrolyte and fluid imbalances, metabolic acidosis (may be profound) <i>Endocrine</i> : Hyperglycemia, acutely <i>Hematopoietic</i> : acute leukocytosis (granulocytosis) ^g hypoprothrombinemia, thrombocytopenia, hypocellularity of bone marrow (if biopsied)
Sulfonanilides (nimesulide) [62]	Metabolic/endocrine: hypothermia ^c ; hypoglycemia ^h

^aTable 7 comprises primarily data from case reports, case series, and retrospective reviews. Often, only severe or unusual cases are reported in the literature

^bMefenamic acid is more likely to produce seizures, compared with other NSAIDs, with >1/3 of patients overdosing on mefenamic acid having seizures [32]

^cGenerally, dose of >400 mg/kg of ibuprofen are required to produce significant toxicity [32]

^dBilirubin may be falsely elevated due to NSAID metabolites that interfere with the assays for bilirubin [63, 64]

^eNSAIDs are known to uncouple oxidative phosphorylation in laboratory studies, so one would expect to see hyperthermia, but this is not generally seen clinically. In severe overdose, hypothermia following coma is more commonly reported than hyperthermia. Hypothermia has also been reported with nimesulide, even at therapeutic doses, in young children

^fTend to be more toxic than most other NSAIDs; Phenylbutazone is used in veterinary medicine and by equine racetrack workers; oxyphenbutazone is a metabolite of phenylbutazone [30, 33]

^gBone marrow dyscrasias are more characteristic of chronic use

^hBoth hypoglycemia and hypothermia may occur after a single therapeutic dose, as well

function tests. Bilirubin may be falsely elevated after overdosage of some NSAIDs [38].

In the older literature, many acute NSAID overdose cases occurred with significant co-ingestion of salicylate, and in the reported fatalities involving NSAIDs, significant salicylate toxicity was often noted; therefore, it is important to assess for concomitant salicylism [33]. Similarly, acetaminophen levels and liver function tests should be assessed to assess for concomitant acetaminophen toxicity (See chapters on Salicylate and Acetaminophen). Diflunisal, a salicylic acid derivative, cross-reacts with some salicylate assays and may produce a false positive for salicylate. Laboratory studies for NSAID concentrations are not generally available and are not likely to be of clinical utility in the acute management. Further, the once advocated nomogram to assess severity of ibuprofen toxicity, based on ibuprofen concentrations, is not useful [4].

Urine studies: Urinalysis may reveal proteinuria and hematuria. Phenylbutazone toxicity has been associated with red-discoloration of the urine, due to a rubazonic acid metabolite [65]. Generally, rapid urine drug screens (enzyme-linked immunoassays) are of limited value. Further, many rapid urine drug screens may produce false positive cannabinoid screens after the use of NSAIDs. If a patient is critically ill, GC/MS may be helpful at detecting co-ingestants as well as NSAIDs.

Imaging studies: Computed tomography (CT) may be useful in the patient with altered mental status of uncertain etiology but is not uniformly necessary for patients known to have overdosed on NSAIDs. Chest radiographs may be helpful for patients with suspected pulmonary edema, ARDS, or aspiration pneumonitis or pneumonia. Ultrasound of the kidneys or liver may be helpful in assessing renal or hepatic failure, respectively, but are not uniformly required.

Treatment of Acute Overdose

Treatments for salicylate and acetaminophen toxicity are not included in this chapter; the treatment of these toxicities differs significantly from what is described below, please refer to these chapters, specifically, if a patient suffers from salicylate or acetaminophen poisoning.

General: Treatment is primarily supportive and expectative. Watch for respiratory compromise. Patients with significant NSAID ingestions may show evidence of GIBs due to the risk of GI irritation, ulceration, and bleeding which may be attenuated by employing an H₂-receptor antagonists [1, 34] (Grade I recommendation). Hypotension generally responds to intravenous fluids, but occasionally vasopressors are employed [56, 57]. Wood et al. report a case of vasopressor-resistant hypotension, eventually resulting in cardiac arrest and death, after massive ibuprofen overdosage [47]. Since functional adrenal insufficiency has been reported in a patient with massive NSAID overdose, hypotension with a concomitant low cortisol level could be treated with systemic steroids [57]. Extracorporeal membrane oxygenation has been utilized for cardiovascular support in the treatment of massive ibuprofen overdose with cardiac failure [56]. Severe metabolic acidosis can be treated with fluid resuscitation and bicarbonate; occasionally, renal replacement therapy is necessary (see below) [47, 57]. Liver transplantation has been utilized to treat fulminant hepatic failure from NSAIDs [46, 66].

Elimination: Oral administration of activated charcoal, without gastric emptying, may reduce NSAID absorption if patients present within 1 h of ingestion and if the airway is protected (e.g., patient is alert or endotracheally intubated for depressed mental status). However, it is unknown if charcoal administration alters the outcome in these patients. Because most NSAIDs are highly protein bound and extensively metabolized, forced diuresis, urinary alkalization, and hemodialysis are generally not indicated to enhance drug

elimination. When studied, these methods do not appear to alter clearance significantly [31, 32, 55]. However, patients with severe acid/base abnormalities, severe electrolyte abnormalities, or acute renal failure may benefit from renal replacement therapy (e.g., high-flux hemodialysis, sustained low efficiency dialysis, continuous hemofiltration, etc.) [30–32, 35, 47, 55]. When renal failure occurs, hemodialysis may be required for weeks to months, but it is generally reversible [52]. Virji, et al. report on a case of severe phenylbutazone poisoning treated with plasmapheresis, but this is not generally performed [61].

Intravenous lipid emulsion therapy (LET) has been used to treat naproxen and ibuprofen toxicity in dogs (case report and series in veterinary literature) [67, 68]. Since most cases of human overdose are not life-threatening, LET is generally unnecessary; however, LET could be tried if cardiac arrest resulted from an overdosage of a lipophilic NSAID, such as ibuprofen or naproxen. Its benefit, if any, following NSAID overdose is strictly theoretical. There are no data indicating that it is beneficial or improves outcome in these patients.

Indications for ICU Admission After NSAID Overdose (Patients May Be Transferred Out of the ICU, Once These Resolve)

Seizures
 Encephalopathy (agitation, psychosis, coma)
 Angioedema with impending airway compromise
 Respiratory failure
 Pulmonary edema or ARDS
 Hemodynamic instability (hypotension, shock, dysrhythmias)
 Gastrointestinal hemorrhage
 Fulminant hepatic failure
 Renal failure with clinical compromise
 Significant electrolyte or acid/base disturbances (e.g., severe metabolic acidosis)
 Multiple organ failure

Special Populations

Geriatric: Elderly patients are known to be more susceptible to the adverse effects of NSAIDs, such as renal toxicity and central nervous system effects. Rarely, NSAIDs produce confusion, hallucinations, and psychoses [69].

Pediatric: Although the rate of life-threatening and fatal events from overdosage of ibuprofen (1.6%) is much less than that of acetaminophen (5.6%) and aspirin (5.9%) in adults; these rates are similar and much lower (approximately 0.4% of reported overdoses for each agent are life-threatening) in children [16]. This is likely due to the higher frequency of unintentional overdoses in children compared with adults. Adolescents may be more susceptible to seizures after mefenamic acid overdose, compared to adults [45]. Randomized controlled trials show an increased risk of renal failure in children taking ibuprofen for fever [16].

Neonatal: There are several reports of iatrogenic overdosage of indomethacin in premature infants, due to the use of indomethacin to treat patent ductus arteriosus (PDA) and to prevent intracranial hemorrhage (ICH). There is concern about indomethacin decreasing mesenteric, cerebral, and renal blood flow; altering platelet and renal function; and disrupting gastric mucosal integrity. In fact, there have been anecdotal reports of necrotizing enterocolitis (NEC) and intestinal perforations with suspected causal contribution from indomethacin. Following planned treatment with indomethacin, patients may experience transient renal impairment, with decreased diuresis, edema, hyponatremia, and hyperkalemia. Narayanan et al. performed a retrospective review of iatrogenic tenfold overdoses of intravenous indomethacin to 4 premature infants (secondary to dosing error) and compared the cases to a large population of premature infants who received appropriate intravenous indomethacin dosing [70]. All 4 patients received only one dose of a tenfold dosing error, with 3 patients experiencing transient drops in urine output and 2 experiencing

transient increased BUN or creatinine; however, none experienced NEC, ICH, or chronic lung disease [70]. Due to the low number of patients (4 patients, with one dosing error each), this data is similar to a case series of 4, and it is difficult to be completely reassured by this data due to the rarity of NEC. Schuster et al. report on a preterm infant who received a single 100-fold overdose of indomethacin for the treatment of PDA. The infant experienced transient renal failure with oliguria and mild hyponatremia and hyperkalemia, with full resolution by 4 days [71].

Obstetric: A large epidemiological study found that nonselective and selective NSAIDs may lead to abortion in the first trimester, with an odds ratio of 2.4 (95% confidence interval 2.1–2.8), compared with pregnant women not taking NSAIDs. Misoprostol, which is sometimes given with NSAIDs for GI protection, should not be administered to pregnant patients due to the risk of miscarriage [15].

Nonsteroidal anti-inflammatory drugs may delay labor, may prematurely close the ductus arteriosus, and may increase blood loss at delivery. Pregnant patients are at increased risk of fetal ductus arteriosus closure as the pregnancy progresses. Indomethacin, diclofenac, and naproxen are known to produce premature closure of the ductus arteriosus. With closure, fetal ultrasound may reveal dilation of the right ventricle, absence of flow in the pulmonary trunk, tricuspid regurgitation, pulmonary insufficiency, or oligohydramnios. The fetus may develop pulmonary hypertension [72–74]. When severe, fetal hydrops and death ensue [72]. Therefore, NSAIDs generally should not be administered during the last trimester [15, 16]. Intrauterine fetal exposure to NSAIDs may also produce hyponatremia and hyperbilirubinemia, recognized at delivery [72, 75].

Lactating mothers may take nonselective and selective NSAIDs, as levels of celecoxib and ibuprofen have been shown to be very low in breast milk [15].

Key Points in Overdosage

Most NSAID overdoses do not produce life-threatening toxicity.

Phenylbutazone and oxyphenbutazone are more toxic than other NSAIDs.

Mefenamic acid overdoses are commonly associated with seizures (much more so than other NSAIDs).

When massive NSAID overdosage occurs, it may be life-threatening.

Critical care is required when the NSAID overdose results in: encephalopathy, status epilepticus, respiratory failure, hypotension, dysrhythmias, cardiac failure, GI bleeding, GI perforation, hepatic failure, renal failure, significant metabolic acidosis or electrolyte abnormalities, cytopenias, and ischemia.

Severely poisoned patients may acutely have fixed, pin-point pupils yet proceed to a full neurological recovery.

NSAID overdosage may produce psychosis, especially in the elderly.

Some NSAIDs may falsely elevate the serum bilirubin concentrations (assay dependent).

Remember to assess for concomitant salicylate and acetaminophen toxicity, as the treatment for these poisonings differs from the treatment of NSAID poisoning.

Renal replacement therapy can be commenced for severe metabolic acidosis but is unlikely to facilitate significant removal of NSAIDs.

generally be taken, although the first dose should be taken under medical supervision.

- *Pregnancy*: Avoid NSAIDs. When NSAID use is essential, limit the dose during early pregnancy because of the risk of miscarriage and in late pregnancy because of the risk of increased blood loss and closure of the ductus arteriosus.

Indications for ICU Admission in Opioid**Poisoning**

Requirement for mechanical ventilation
Symptomatic poisoning with methadone, buprenorphine, or other extended-release or long-acting opioid
Requirement for naloxone infusion
Acute lung injury or other hypoxic insult
Cardiovascular manifestations of hypotension, bradycardia, QRS prolongation, or QT lengthening requiring treatment
Seizures, life-threatening symptoms attributed to serotonin toxicity
Neonatal withdrawal
Symptomatic body packers
Potential complications of prolonged coma, brain injury, compartment syndrome, and severe rhabdomyolysis with risk or evidence of renal failure

Criteria for ICU Discharge in Opioid Poisoning

Resolution of ventilatory depression with adequate respirations
Resolution of acute lung injury or other hypoxic insult
Cessation of a naloxone infusion
Resolution of hypotension or bradycardia
Resolution of neonatal withdrawal

Key Points in Opioid Poisoning

1. Miosis is *not* present in all opioid users and cannot be used diagnostically.
2. Naloxone should be administered in small amounts (starting with 0.04–0.05 mg if opioid dependent) to avoid withdrawal. If opioid withdrawal results, do not attempt to reverse the withdrawal symptoms with another opioid. Allow naloxone's effect to wane spontaneously (typically 20–60 min).
3. Methadone and other semisynthetic or synthetic opioids do not cross-react with the standard urine opioid drug assay.

Opium production dates back to the fourth century BC, and the first written documentation of its use dates to the writings of Theophrastus in the third century BC [1, 2]. Opium, which is the crude extract of the opium poppy plant, *Papaver somniferum*, was used for medicinal, recreational, and religious purposes. Morphine was isolated from opium in 1806 and was named after Morpheus, the Greek god of dreams. Diacetylmorphine, also called *heroin*, ironically was synthesized in the search for a safer, less addictive opioid. The endogenous opioid peptides, enkephalin, β -endorphin, and dynorphin, were isolated sequentially starting in 1975 [3].

Although the medicinal benefits of opioids are undeniable, opioid use is fraught with tribulations for the patient and for society. Poisoning is now the leading cause of injury death in the USA, with 41% (16,917 deaths) of poisoning deaths in 2011 involving opioid analgesics [4, 5]. Recent data from the Researched Abuse, Diversion, and Addiction-Related Surveillance (RADARS) System revealed significant increases in opioid prescriptions and diversion and abuse of prescription opioids between 2002 and 2010 [6]. There has been a slight reduction from 2011 to 2013, suggesting potential benefit to local, regional, state, and federal interventions that have been implemented to address the growing problem. In addition, the rates of opioid-related deaths increased from 2002 to 2006, plateaued from 2006 to 2008, then slightly decreased from

2009 to 2013. Despite these improvements in prescription opioid-related deaths, the rates of heroin-related deaths (from the National Poison Data System) steadily increased from 2010 to 2013. This most likely occurred due to the reduced availability of prescription opioids, leading to the use of this cheaper and more available substitute [6]. This chapter focuses on the clinical issues concerning the acute and chronic adverse effects of opioid use.

The term *opioid* refers to an agent that is capable of specific binding to an opioid receptor. This term is inclusive and alludes to all such agents, whether they are endogenous peptides, plant or animal-derived, or synthetic, and does not specify whether the agent is an agonist or an antagonist at the receptor. *Opiates* are the subclass of drugs derived from the opium poppy plant. More than 20 naturally occurring opiates can be extracted from this plant, including morphine, codeine, and thebaine. Semisynthetic opioids, such as heroin, oxycodone, and hydromorphone, are derived from structural alteration of morphine's base structure with functional groups (Fig. 1). For example, heroin has acetyl functional groups added at both positions 3 and 6 to make diacetylmorphine.

Endogenous opioid peptides include three individual classes of peptides – enkephalins, dynorphins, and endorphins – that serve as innate agonists of the various human opioid receptors. The term *narcotic*, derived from the Greek word meaning “stupor” or “numbness,” is used to refer to any drug that induces sleep, although it can also refer to other illegal drugs of abuse including cocaine. Although this use of the term encompasses one of the primary clinical roles of the opioid agonists, the term often is used to designate an illicit substance.

Pharmacology

Opioids interact with opioid receptors (Table 1) to modulate their various clinical effects. Opioid receptors may be categorized based either on location within the body or on the binding affinities for various endogenous or exogenous opioid agents.

Fig. 1 (continued)

Fig. 1 Chemical structures of opioids discussed in the text

Table 1 Interaction of opioids and their receptors in modulating various clinical effects

Opioid receptors	Agonists	Clinical effects	Location
μ_1, μ_2	Morphine	μ_1 – supraspinal analgesia, peripheral analgesia, euphoria, sedation, prolactin release	Periaqueductal gray matter, nucleus raphe magnus, medial thalamus, limbic system, medulla
		μ_2 – spinal analgesia, respiratory depression, physical dependence, gastrointestinal dysmotility, miosis, pruritus, bradycardia	
$\kappa_1, \kappa_2, \kappa_3$	Ketocyclazocine – κ_1	κ_1 – spinal analgesia, miosis, diuresis	Spinal cord, antinociceptive regions of brain as listed above, substantia nigra
	Pentazocine, salvinorin A – κ_2	κ_2 – psychotomimesis, dysphoria	
	Nalorphine – κ_3	κ_3 – supraspinal analgesia	
δ	Enkephalins – δ_1, δ_2	Spinal and supraspinal analgesia, cough suppression, modulate motor activity	Nigrostriatal pathway
σ (no longer considered opioid receptor)	Dextromethorphan, pentazocine, ibogaine	Spinal analgesia, psychotomimesis, movement disorders	Hypothalamus, limbic forebrain, midbrain, cerebellum, brainstem, hippocampus

Similarly, opioids may be classified by their receptor preference or by pharmacologic characteristics. Because of this multiplicity of receptor and drug characteristics, most opioids produce a wide array of clinical effects. Opioid receptor families are identified in the central nervous system and are differentiated by anatomic location and function. The opioid receptor is stereospecific, and only the levorotatory (–) opioid isomers elicit clinical effects. The μ receptor, which exists in two subtypes, μ_1 and μ_2 , is the binding site for the endogenous ligand β -endorphin [7]. When stimulated, the μ_1 receptor subtype produces supraspinal (e.g., brain) analgesia, euphoria, and peripheral anti-inflammatory effects. Stimulation of the μ_2 receptor subtype mediates spinal-level

analgesia and is the cause of most of the negative effects of opioid use, such as respiratory depression, miosis, constipation, pruritus, bradycardia, and physical dependence. These receptor subtypes are localized to the areas of the brain responsible for analgesia (periaqueductal gray matter, nucleus raphe magnus, medial thalamus), euphoria (limbic system), and respiratory depression and cough (medulla) [8, 9]. In the periphery, the μ_2 receptor is found in the gastrointestinal tract and peripheral terminals of nerve fibers in human synovia and immune cells, such as lymphocytes, macrophages, and mast cells [10].

Although the κ receptors are named for their ability to bind ketocyclazocine, their endogenous ligand is dynorphin A [11]. κ receptors are found

Table 2 Opioids available for clinical use^a

AGENT	CLASS	COMMENTS
Agonists		
Codeine	Natural	Often combined with acetaminophen; used as antitussive
Dextromethorphan (Robitussin [®] DM)	Semisynthetic	Antitussive; abused for psychoactive effects
Fentanyl (Sublimaze [®])	Synthetic	Very short acting
Heroin	Semisynthetic	Diacetylmorphine, more euphoric than morphine
Hydrocodone (Vicodin [®] , Zohydro [®] ER)	Semisynthetic	Potent opioid for chronic pain therapy
Hydromorphone (Dilaudid [®])	Semisynthetic	Potent opioid for chronic pain therapy
Methadone (Dolophine [®])	Synthetic	Very long acting (approximately 24 h), QT interval prolongation
Morphine	Natural	Gold standard opioid
Oxycodone (Percocet [®])	Semisynthetic	Sustained-release preparation (OxyContin [®])
Tramadol (Ultram [®])	Synthetic	Seizures may occur
Antagonists		
Naloxone (Narcan [®])	Semisynthetic	Short acting (0.5 h)
Naltrexone (Trexan [®])	Semisynthetic	Very long acting (24 h)
Mixed Agonists-Antagonists		
Butorphanol (Stadol [®])	Semisynthetic	Not widely used class
Nalbuphine (Nubain [®])	Semisynthetic	
Partial Agonist		
Buprenorphine (Buprenex [®] , Suboxone [®])	Semisynthetic	Gaining wide acceptance in opioid substitution therapy

^aExamples of US trade names are given in parentheses. These vary from country to country

primarily in the spinal cord but also are found supraspinally in the antinociceptive regions of the brain, substantia nigra, cortex, and cerebellum. The functional opioid receptors in the cerebellum may be involved not only in motor control and pain but also in motivational aspects of behavior and cognitive functions [12–14]. The κ_1 receptor subtypes produce primarily spinal analgesia, miosis, and diuresis (via inhibition of antidiuretic hormone release). Agonism at the κ_2 receptor subtype is associated with dysphoria and psychotomimesis. The κ_3 receptor subtype, in contrast to the κ_1 receptor, provides supraspinal analgesia [15]. κ receptor-mediated analgesia occurs independent of μ receptor activity, as evidenced by the inability of μ -selective antagonists to reverse κ effects [16]. Dysfunction of the κ opioid receptor system may underlie some of the neurochemical mechanisms of drug abuse. Chronic administration of drugs with positive reinforcing properties, such as morphine, amphetamine, and cocaine, increases brain dynorphin

levels, which suggests that dynorphin may be part of homeostatic mechanisms to oppose the mood-enhancing and reinforcing effects of these drugs of abuse [17, 18].

The δ receptor affects spinal and supraspinal analgesia. δ_1 and δ_2 receptor subtypes are established, and the enkephalins are their endogenous ligands [19]. Other δ receptor effects include alteration of nigrostriatal dopamine release, which modulates motor activity [20], and inhibition of the cough reflex [21].

A variety of opioid agonists are available for clinical use (Tables 2 and 3). Although useful for classification, whether the drug is natural, synthetic, or semisynthetic has little relevance to the clinical effects or pharmacology of the individual opioid agonists. Their predominant roles are in the management of acute and chronic pain syndromes or substitution therapy for illicit opioid use (e.g., methadone, buprenorphine). Their primary differences relate to their duration of effect, although most of the agents used for acute pain

Table 3 Comparison of opioid analgesics with respect to dosage and duration of action [2, 22, 23]

Drug	Equianalgesic doses		Plasma half-Life (HR)	Duration of effect (HR)
	(mg)			
	PO	Parenteral		
Codeine	200	100–130	2–4	3–5
Fentanyl (Sublimaze®)	Variable ^a	0.1	3–4	<1
Heroin (diacetylmorphine)	60	5	0.5	2–3
Hydromorphone (Dilaudid®)	7.5	1.5	2–3	3–5
Methadone (Dolophine®)	Variable ^b	Variable ^b	15–40	12–24
Morphine	30	10	2	2–3
Oxycodone	20–30	N/A	2	3–5

PO, oral; Parenteral, includes subcutaneous, intramuscular, and intravenous

Opioid equianalgesic dosing in this table are approximate and should be used only as a guideline. They are based on single-dose studies in opioid-naïve patients with acute pain. Incomplete cross-tolerance exists among different drugs. When changing drugs, it is often recommended to start with a 50% lower dose than the equianalgesic dose and then individually titrate to clinical response

^aNoninjectable fentanyl products are for opioid tolerant patients only. Conversion between different noninjectable fentanyl products (e.g., transmucosal, buccal, nasal spray, sublingual, transdermal) should not be done

^bMethadone conversion is highly variable and depends on factors such as patient tolerance and length of dosing (acute vs. chronic dosing)

management are short acting, with duration of approximately 3–5 h after a single dose [2]. Agents used for other indications typically are longer acting and the ability to predict the duration of effect after chronic use is limited [2].

Buprenorphine is a partial agonist with complex pharmacology predominated by partial agonism at the μ opioid receptor; its effects are also mediated through antagonism at κ or δ opioid receptors and interaction with opioid receptor-like receptors [24]. Partial agonists can be effective opioid analgesics in opioid-naïve patients. In opioid-dependent patients, buprenorphine competes with the existing opioid for the μ receptor and, due to higher binding affinity of buprenorphine for the μ receptor, can produce the opioid withdrawal syndrome [25].

Diphenoxylate is a congener of meperidine that is used as an agent to reduce gastrointestinal motility. Because of its insolubility, diphenoxylate acts locally within the gastrointestinal tract. Typically, diphenoxylate is combined with atropine (Lomotil) for the treatment of diarrhea. Opioid and anticholinergic effects may occur in overdose.

Delayed and recurrent presentation may be noted secondarily to the delay in gastric emptying by both agents. Naloxone is effective in reversing recurrent central nervous system and respiratory depression. One patient was noted to present 18 h after ingestion with marked signs of atropinism, whereas other patients presented with delayed respiratory depression [26]. Because of the possibility of delayed and severe effects, all patients with potentially large ingestions of diphenoxylate-atropine should be admitted for monitored observation (Level III).

Certain agents with opioid activity also have additional pharmacologic effects mediated by nonopioid mechanisms. Dextromethorphan, an abused, nonanalgesic, opioid antitussive agent [27, 28], at high doses produces sedation and a dissociative state similar to that produced by phencyclidine [29, 30]. This effect is due to noncompetitive antagonism at *N*-methyl-D-aspartate (NMDA) receptors by an active metabolite dextrorphan, which binds to the phencyclidine site on the NMDA receptor. This produces concentration-dependent inhibition of calcium influx through this receptor-linked ion channel,

causing psychotomimesis [31]. The results of an in vitro study suggested that dextromethorphan may exert anticonvulsant and neuroprotective effects by reducing Ca^{2+} influx through voltage-activated Ca^{2+} channels [32]. Dextromethorphan also blocks presynaptic serotonin reuptake and may lead to serotonin toxicity, specifically in patients taking selective serotonin reuptake inhibitors or monoamine oxidase inhibitors [33, 34]. Tramadol overdose may produce mild serotonergic effects [35, 36], and a retrospective, observational case series suggests that lethal serotonin toxicity is unlikely [37].

Other Opioids

Several opioids, including pentazocine, propoxyphene, and meperidine, have previously been used extensively; however, they are now used extremely rarely or have been discontinued altogether in the USA.

Pentazocine is a mixed opioid agonist–antagonist (κ agonist, μ antagonist) that may produce pain relief in an opioid-naïve person but produce a withdrawal phenomenon in a patient dependent on a μ opioid agonist [2]. Propoxyphene is an opioid agonist that may act as a proconvulsant and an arrhythmogen [38]. The parent drug and its metabolite norpropoxyphene possess myocardial sodium channel-blocking effects analogous to those of class I antidysrhythmics. Tramadol may also cause sodium and potassium channel blockade leading to QRS and QTc prolongation, respectively [39]. Meperidine is an opioid agonist that causes substantial euphoria and therefore carries a significant addictive potential; as such, it has been removed from the formulary at many health care institutions [40]. Normeperidine, the renally eliminated metabolite of meperidine, is a proconvulsant. Patients who use high doses of meperidine, especially patients who have renal insufficiency, are at risk for developing normeperidine toxicity [41]. In addition, meperidine inhibits reuptake of serotonin and, especially in combination with other serotonin agonists, may lead to serotonin toxicity [40, 42]. Intravenous meperidine has

been reported to cause QTc prolongation and ventricular dysrhythmia [43, 44].

Pathophysiology and Clinical Presentation

At sufficient doses, all opioid agonists produce the opioid toxidrome, a constellation of signs consisting of depression of mental status, ventilatory rate, and tidal volume; miosis; and reduced bowel motility. Many of these effects are due to the μ receptor-mediated reduction in sympathetic autonomic tone. Patients exposed to opioids, whether therapeutically or otherwise, typically present with bradycardia or hypotension, generally to a degree that is appropriate for their level of consciousness. Profound hemodynamic disturbances are unlikely to be the direct effect of an opioid agonist but represent an epiphenomenon secondary to hypoxia.

Most opioid-induced mortality relates directly to hypoxia, and patients rarely suffer significant discomfort from the other acute effects of opioids (e.g., gastrointestinal hypomotility, miosis). The opioid-induced reduction in ventilation occurs secondary to a reduced sensitivity of the medullary chemoreceptors to hypercapnia and hypoxia [45]. This effect is dose related, and in sufficient dose agents with full agonist effect may produce apnea. Opioid agonist–antagonists and partial agonists have ceilings on their ventilatory depressant effects [46]. After overdose with these agents, life-threatening hypoventilation is rare, although it may still occur in select patients, particularly children [47]. The ventilatory effects may manifest as a decreased respiratory rate, decreased tidal volume, or both. The initial ventilatory effects of the opioids commonly include a reduction in tidal volume, which is difficult to assess and often overlooked [48]. Because all currently available μ_1 agonists also exert effects at the μ_2 receptor, all opioids should be expected to produce respiratory depression.

Miosis is a relatively consistent finding among patients exposed to opioid agonists and likely results from a complex excitatory action on parasympathetic nerves [49]. Alternatively, patients

using opioids may occasionally present with mydriasis, so this finding cannot be relied on diagnostically. For example, patients using heroin in combination with cocaine, called a *speedball*, may present with dilated pupils depending on the relative balance of the two agents. Patients who have asphyxia or hypoxic encephalopathy also may have mydriasis.

Nausea and vomiting result from stimulation of dopamine-2 receptors at the chemoreceptor trigger zone. This effect has not been proved to be alleviated by low-dose naloxone [50]. Opioid agonists reduce gastrointestinal motility, producing constipation and bloating. These effects occur through increasing myenteric smooth muscle tone mediated through μ opioid receptors and can be reversed by low-dose oral naloxone, which is poorly bioavailable and rarely induces any opioid withdrawal symptoms [51]. Other agents that could be used to reverse constipation include methylnaltrexone, alvimopan, and naloxegol, opioid receptor antagonists that do not cross the blood-brain barrier in humans (Level I) [52]. These agents reverse the unwanted peripheral opioid effects, including constipation, without reversing the desired central effects, such as analgesia [53]. Little gastrointestinal tolerance develops, and patients who chronically take opioids generally remain constipated [54].

Although the cardiovascular effects of opioids are mediated primarily by regulation of the autonomic nervous system, certain opioids, such as propoxyphene, may be directly cardiotoxic following overdose. Historically, quinine-adulterated heroin was associated with cardiac dysrhythmias and death [55, 56].

Acute respiratory distress syndrome, formerly called acute lung injury or *noncardiogenic pulmonary edema*, is associated commonly with opioid overdose. Its cause is likely multifactorial, and its association with naloxone administration, although likely valid, is probably overestimated. Pulmonary edema is unmistakably described in autopsy series in the 1880s, long before the introduction of naloxone. The association more probably relates to the improved auscultative ability of the examining physician after reinstitution of spontaneous ventilation with naloxone. Still,

precipitation of a fulminant opioid withdrawal syndrome after naloxone may produce a catecholamine surge sufficient to impair myocardial relaxation and produce transitory congestive heart failure [57]. Canine models suggest that an elevated PCO_2 at the time of opioid-antagonist reversal of opioid-induced respiratory depression is associated with a more dramatic increase in mean arterial blood pressure and heart rate, suggesting a role for assuring adequate ventilation prior to naloxone administration (Level II-3) [58].

Another mechanism implicated in opioid-associated acute respiratory distress syndrome involves inspiration against a closed airway glottis, the so-called Müller maneuver. Such a respiratory effort, occurring when the larynx is occluded due to pharyngeal laxity, creates negative intrathoracic pressure and may result in fluid being drawn into alveoli through hydrostatic forces [59]. Alternatively, hypoxic damage producing an alveolar capillary leak syndrome may result in pulmonary edema.

Rapid administration or high doses of fentanyl can produce life-threatening chest wall rigidity. This effect occurs most commonly during anesthesia but also occurs in intravenous drug users who unknowingly inject fentanyl-adulterated heroin. Although incompletely characterized, it seems that the locus coeruleus and the caeruleospinal noradrenergic pathways in the spinal cord are responsible [60]. Naloxone produces a variable, but generally beneficial, response [2].

Although not part of the opioid toxidrome, seizures are another rare manifestation of therapeutic opioid use. After opioid overdose, patients may seize as a result of hypoxia or as a direct result of a drug or its metabolite. Accumulation of proconvulsant metabolites of certain opioids, such as tramadol and meperidine, cause seizures. Morphine injected into various regions of the brain of experimental animals causes epileptic activity not inhibited by naloxone [61]. In humans, only neonates have morphine-induced seizures, presumably due to the immaturity of the blood-brain barrier [62].

Though not direct effects of opioids themselves, many subacute complications commonly occur following significant opioid exposures

related both to prolonged immobility and to CNS and respiratory depression. Prolonged immobility may lead to rhabdomyolysis, characterized by skeletal muscle injury with release of intracellular contents such as myoglobin, creatine kinase, lactate dehydrogenase, aminotransferases, and potassium [63]. In addition to skeletal muscle injury, cardiac rhabdomyolysis may occur in rare instances, and, coupled with metabolic disturbances, may lead to cardiac dysrhythmias [64]. Acute rhabdomyolysis may be complicated by compartment syndrome, peripheral neuropathy, acute kidney injury, and disseminated intravascular coagulopathy [63, 65]. Prolonged respiratory depression following opioid overdose may produce acute cerebral hypoxic-ischemic injury [66] and rarely, delayed posthypoxic leukoencephalopathy [67]. Aspiration pneumonia is another common complication.

Diagnosis

Opioid poisoning is a clinical diagnosis, linking data from the patient's medical and presenting history, physical examination, and, perhaps, response to naloxone therapy. Laboratory data (blood and urine testing) are not necessary for the management of patients with opioid poisoning, other than to assess for concurrent medical conditions or to evaluate complications. In general, urine screens for recreational drugs are of little direct clinical value in the acute setting and they often do not return in a timely fashion. Analytically, they are subject to cross-reactivity with other compounds and may not detect synthetic or semisynthetic compounds. However, drug screens may be helpful for monitoring patients in addiction therapy or on therapy for chronic pain and may be used to establish a dual-diagnosis psychiatric disorder. Coingestants, such as ethanol and acetaminophen or aspirin, also must be considered, and laboratory testing ordered as indicated. The differential diagnosis of opioid poisoning includes other causes of depressed mental status, such as intracranial hemorrhage; postictal state; sepsis; postanoxic encephalopathy; hypoglycemia; hypothermia; and poisoning by various agents, including carbon monoxide, clonidine,

and other imidazolines, phenothiazines, atypical antipsychotics, and sedative-hypnotics (benzodiazepines and ethanol). Of note, some severely hypotensive patients presumed to be septic turn out to be late presenting opioid intoxicated patients.

Treatment

Proper airway management is crucial to managing opioid-poisoned patients. Patients experiencing ventilatory depression or hypoxia require either mechanical respiratory support or antidote administration. Use of nasopharyngeal or oral airway support can be considered in obtunded patients with non-life-threatening ventilatory depression and the absence of a gag reflex. Because both of these maneuvers can result in emesis, however, which can be life-threatening in a patient without an appropriate protective reflex, they should be used only with extreme caution. More appropriately, patients who are hypoventilating or hypoxic should be ventilated initially using a bag-valve-mask device with 100% oxygen supplementation. The decision to place an endotracheal tube or laryngeal mask airway depends on the patient's clinical condition, his or her response to less aggressive means of ventilation, response to naloxone, and the environment in which care is delivered.

Patients experiencing inadequate ventilation, as defined by an inadequate respiratory rate or tidal volume, may benefit from the administration of an opioid antagonist, such as naloxone. In adult patients who are unconscious for undefined reasons, a respiratory rate of less than 12 breaths/min is most predictive of response to naloxone [68]. Although this finding is neither highly sensitive nor specific, opioid poisoning rarely is diagnosed in patients with respiratory rates at or above normal. Because unneeded treatment with naloxone, regardless of the dose delivered, is rarely detrimental in patients who are not opioid dependent, a therapeutic trial in such patients with depressed respiration or mental status generally is warranted (Level II-3). Alternatively, in opioid-dependent patients, emesis due to precipitated opioid withdrawal in the setting of a

non-naloxone-responsive etiology for mental status depression (e.g., ethanol intoxication) risks pulmonary aspiration. Regardless, if chronic opioid use cannot be determined, judicious administration of small doses of naloxone, with titration upward to effect, should allow the therapeutic trial to be aborted if signs of withdrawal develop (Level III). In the USA, depending on the population served and region (e.g., availability of methadone maintenance therapy), the prevalence of opioid dependence varies widely, so the empirical use of naloxone must be tailored to the clinical setting. Naloxone is not only beneficial in treating tramadol-induced respiratory depression and somnolence [69, 70] but also preventing tramadol-induced seizures in both animal models [71] and humans [72]. Certain opioids, primarily buprenorphine, will respond to naloxone less predictably and in a nonlinear fashion compared to other opioid receptor agonists. Standard naloxone dosing will often not result in clinical improvement in patients with buprenorphine toxicity [73], as reversal tends to occur along a bell-shaped dose–response curve, with doses of 2–4 mg intravenous naloxone being effective and larger doses exacerbating the respiratory depression. The clinical pharmacology of naloxone and other opioid antagonists is discussed in detail in ► Chap. 157, “Opioid Receptor Antagonists.”

Dosing of Naloxone

Opioid dependence unlikely: 0.4 mg IV, escalating to 10 mg

Opioid dependence possible: 0.04–0.05 mg IV, additional doses every 1–2 min until response or signs of withdrawal

Positive response, short-acting opioid suspected: observe for resedation for 6 h

Positive response, with resedation: redose as needed or continuous infusion starting at two-thirds of the initial reversal dose hourly, titrated to effect IV, intravenously

The need for gastrointestinal decontamination is case specific and controversial (Level II-3). If given within the first hour postingestion it may decrease the absorption of ingested opioids.

However, it is unknown if it alters the clinical course or outcome in such situations. The administration of oral activated charcoal to nonintubated patients should be done cautiously because mental status depression increases the risk of pulmonary aspiration. The only opioid-exposed patients likely to benefit from more aggressive gastrointestinal decontamination are those who are attempting to conceal large amounts of drug in their gastrointestinal tract (e.g., *body packers*) to avoid detection by law enforcement. For details of the management of non-ICU-related aspects of opioid poisoning the reader is directed to a comprehensive general clinical toxicology text [74].

Special Populations

Children

Neonatal opioid withdrawal syndrome occurs in newborns of opioid-using mothers. Although it is similar to the adult opioid withdrawal syndrome in many respects, fever, myoclonic jerks, and life-threatening seizures are unique to the neonatal syndrome. The withdrawal syndrome typically presents within minutes to 2 weeks after birth. The half-life of the particular opioid used by the mother directly correlates with the time at which opioid withdrawal symptoms manifest in the neonate [75]. Treatment of neonatal opioid withdrawal includes various regimens, such as paregoric, phenobarbital, diazepam, diluted opium tincture, and methadone. Further discussion of this withdrawal syndrome can be found in ► Chap. 27, “Withdrawal Syndromes.”

Pregnant Patients

Reversal with naloxone of a pregnant opioid-tolerant patient who is acutely opioid intoxicated may precipitate uterine contractions and possible induction of labor [76]. Slow titration of naloxone will minimize this effect. Pregnant women who are opioid dependent are generally maintained on methadone or buprenorphine until after delivery.

Elderly Patients

Because of altered liver or kidney function in elderly patients, the pharmacokinetics of certain opioid agents may be unpredictable, and toxic effects may develop. Morphine is metabolized by the liver; any patients with cirrhosis or on medications that can interfere with liver function may be at risk for increased toxicity. In particular, elderly patients in the intensive care unit receiving ranitidine and morphine may have enhanced effects leading to confusion and hallucinations [77, 78]. In one study in humans, ranitidine was found to inhibit morphine glucuronidation, decreasing the morphine-3-glucuronide (M3G)-to-morphine-6-glucuronide (M6G) ratio and increasing the presence of morphine [79]. The active morphine metabolites, M3G and M6G, are renally excreted. M3G and M6G need to be considered when administering morphine as both metabolites can cause significant toxicity in elderly patients and patients with renal failure [80]. M6G has potent opioid agonist effects and is considered 4–20-fold more potent than morphine. M3G has no antinociceptive properties yet has neuroexcitatory effects (allodynia, myoclonus, seizures) [81].

Salicylate intoxication carries significant morbidity and mortality that are compounded when the seriousness of the situation is not recognized by the treating physician [1]. Progressive central nervous system (CNS) depression demands several immediate, aggressive actions, not just endotracheal intubation and ventilation. A small decrease in arterial pH to 7.3 may be of little consequence to most patients in a critical care unit, but in patients with salicylate intoxication, this decrease may result in rapid shifts of salicylate into the brain and heart, causing surprisingly swift deterioration and death. A decrease in serum drug concentrations is accompanied by clinical improvement in most other drug intoxications, but this frequently is not the case with serious salicylate poisoning. Patients may deteriorate and die as serum salicylate levels decrease.

A successful outcome for a patient with salicylate poisoning frequently requires prolonged physician time at the bedside with rapid responses to frequently changing laboratory and clinical parameters. The intensivist must become familiar with the pathophysiology, pharmacokinetics, potential pitfalls, and treatment options for salicylate intoxication in order to be successful in preventing death.

Sources of Salicylate

Numerous forms of salicylate are available in over-the-counter and prescription preparations (Table 1). Regardless of the product, all of these formulations are converted to salicylate during or shortly after absorption.

Many keratolytic agents contain salicylic acid, and toxicity and death have followed dermal application [2, 3]. Various liniments and some flavoring agents contain methyl salicylate (oil of wintergreen). Death has resulted from the ingestion of these liniments or from exposure to pure methyl salicylate [4]. Although salicylate is poorly absorbed after single ingestions of bismuth subsalicylate, the repeated use of large quantities of bismuth subsalicylate, such as those used in the treatment of diarrhea associated with acquired immunodeficiency syndrome, can result in serum salicylate concentrations in the toxic range.

Pathophysiology

General and Metabolic Effects

Salicylate toxicity produces numerous metabolic derangements (Table 2), including respiratory alkalosis, metabolic acidosis, ketosis, hypokalemia, hypoglycemia, and hyperglycemia. Salicylate stimulates the respiratory center in the brainstem to produce tachypnea, hyperpnea, and respiratory alkalosis [5]. Most adults who present early with acute salicylate toxicity display alkalemia. As toxicity progresses, the onset of metabolic acidosis (described later) first normalizes pH and then produces acidemia as respiratory alkalosis is overwhelmed by acidosis or as respiratory depression ensues from worsening toxicity (e.g., coma, apnea). The coingestion or iatrogenic administration of CNS depressants (e.g., benzodiazepines, opiates) or neuromuscular blockade with controlled mechanical ventilation may blunt hyperventilation and respiratory alkalosis, allowing for clinical expression of only metabolic acidosis [6].

Salicylate impairs adenosine triphosphate (ATP) synthesis through various mechanisms,

Table 1 Salicylate-containing products available as over-the-counter or prescription medications^a

Aspirin (acetylsalicylic acid)
Bismuth subsalicylate
Choline salicylate
Magnesium salicylate
Methyl salicylate (oil of wintergreen)
Salicylic acid
Salsalate (salicylsalicylic acid)
Sodium salicylate
Sodium thiosalicylate
Triethanolamine salicylate

^aAll of these agents undergo conversion to salicylate during or shortly after absorption

Table 2 Toxic actions of salicylate^a

Causes corrosive injury to the gastrointestinal tract
Stimulates respiratory center in the brainstem
Uncouples oxidative phosphorylation
Inhibits tricarboxylic acid cycle
Enhances glycogenolysis
Increases glucose consumption
Inhibits gluconeogenesis
Enhances lipolysis
Prevents activation of vitamin K-dependent coagulation factors
Inhibits platelet aggregation (significant only with aspirin)

^aThese actions are thought to account for most of the clinical syndromes seen with salicylate poisoning. In vitro, additional and often contradictory effects can be seen

and impaired ATP production from mitochondrial toxicity is the common denominator for much of salicylate’s toxicity. A mitochondrion is surrounded by an external and an inner membrane. As electrons travel down the electron transport chain on the inner mitochondrial membrane (cristae), the released energy is used to pump H⁺ ions out of the matrix into the mitochondrial intermembrane space, producing an electrical and pH gradient across the inner mitochondrial membrane. The electrons moving down the transport chain within the mitochondrion eventually combine with oxygen, the terminal electron acceptor, to form water. Meanwhile, hydrogen

ions that have been concentrated within the intermembrane space reenter the mitochondrion through a pore in ATP synthase, a protein spanning the inner membrane, providing the energy needed to generate ATP from adenosine diphosphate (ADP) and phosphate inside the organelle. In mitochondria, ATP production via oxidative phosphorylation normally is “coupled” to oxygen consumption.

Salicylate uncouples oxidative phosphorylation through at least two mechanisms. First, similar to many weak organic acids, un-ionized salicylate crosses the inner mitochondrial membrane to release an H^+ into the matrix, where the pH is higher [7]. The remaining salicylate anion or other anions or both are transported out of the mitochondria. Second, salicylate may cause formation of pores in the inner mitochondrial membrane that are permeable to numerous substances, including H^+ [8]. The end result of these two processes is a decrease in the H^+ gradient across the inner mitochondrial membrane, allowing H^+ ions to reenter the mitochondrial matrix without traveling through ATP synthase, decreasing ATP formation [8]. Electron transport and oxygen consumption continue and even accelerate in an effort to generate ATP in the face of uncoupled oxidative phosphorylation. When uncoupling is severe, hyperthermia may develop as a consequence of heat production rather than ATP generation.

Impairment of ATP production also occurs within the mitochondrial matrix, where salicylate inhibits α -ketoglutarate dehydrogenase and succinic acid dehydrogenase of the tricarboxylic acid (Krebs) cycle [9, 10]. This activity decreases the formation of reduced nicotinic adenine dinucleotide and reduced flavin adenine dinucleotide, the main electron donors for the respiratory chain.

The metabolic acidosis accompanying serious salicylate poisoning is incompletely understood. Glycolysis (anaerobic conversion of glucose to lactate) is accelerated in salicylate poisoning in an attempt to meet ATP requirements in the presence of impaired oxidative phosphorylation. As emphasized by others [11–13], however, the conversion of glucose to lactate does not result in the

production of hydrogen ions, as illustrated in a balanced equation of glycolysis:

Cellular pH and concentrations of substrates influence the amounts of ATP and H^+ produced during glycolysis, but glycolytic production of lactate and ATP is not acidifying, regardless of pH [12, 13]. A large portion of the acidosis of salicylate poisoning most likely results from hydrolysis of ATP:

Just as the hydrolysis of ATP always results in a net production of a H^+ , the synthesis of ATP via oxidative phosphorylation in the inner mitochondrial membrane results in H^+ consumption by the reverse reaction:

During normal metabolism, H^+ consumption via oxidative phosphorylation balances H^+ production from hydrolysis of ATP. Impaired oxidative phosphorylation (from uncoupling and inhibition of the tricarboxylic acid cycle) provides a state in which the hydrolysis of ATP produced in glycolysis generates H^+ faster than they can be buffered, excreted, or, most importantly, consumed via oxidative phosphorylation.

Circulating lactate concentrations are usually within the normal range or are slightly elevated in most patients with salicylate toxicity [14]. Occasionally lactate concentrations can be notably elevated.

The metabolic acidosis of salicylate toxicity is also in part a ketoacidosis [5, 14]. Salicylate stimulates lipolysis and ketone formation. Most patients with salicylate toxicity excrete increased urine ketones that are detected easily by laboratory studies.

Elevated circulating cytokine concentrations have been described in patients with salicylate toxicity [15]. Their role in contributing to disease

is undefined, however, because various cytokines are elevated in the blood of patients who are critically ill from many different causes.

Serum glucose concentrations vary during salicylate intoxication. During serious salicylate intoxication, glucose consumption is increased as glycolytic generation of ATP increases to compensate for impaired oxidative phosphorylation. Increased epinephrine and glucagon secretion results in mobilization of glycogen stores, commonly producing hyperglycemia early in the intoxication. Serum glucose concentrations commonly reach 200–300 mg/dL (11–17 mmol/L). As salicylate toxicity continues, glycogen stores become depleted, and increased glucose demands can be met only by a marked increase in gluconeogenesis. Salicylate is an inhibitor of alanine aminotransferase, preventing the conversion of alanine to pyruvate to fuel gluconeogenesis [16]. Serum glucose concentrations normalize and can reach the hypoglycemic range, especially in children [17, 18] but also in adults [19].

Hypoglycorrhachia and neuroglycopenia are noted in animal models of salicylate toxicity [20], even without hypoglycemia. It has been suggested that some CNS toxicity from salicylate may reflect low CNS glucose concentrations and that this might occur without hypoglycemia.

Most patients with moderate-to-severe salicylate toxicity have hypokalemia, unless severe dehydration, impaired renal function, or rhabdomyolysis has resulted in hyperkalemia. Hypokalemia probably reflects gastrointestinal losses (vomiting) and obligate urinary excretion of potassium, with the salicylate anion or other organic acids or both resulting from toxicity.

A symptomatic adult patient with moderate-to-severe salicylate toxicity typically has a fluid deficit of at least 4–6 L on presentation. Water losses from hyperventilation, diaphoresis, third spacing of fluids in the muscle from rhabdomyolysis, and vomiting are easily underestimated. Failing to rehydrate the patient adequately and maintain adequate intravascular volume is a common error made by treating physicians.

Gastrointestinal Tract and Liver Effects

Aspirin produces corrosive injury to the gastrointestinal tract. Patients with acute intoxications frequently have abdominal pain, vomiting, and hematemesis. Rare reports of gastric perforation after acute aspirin overdose appear in the literature [21, 22]. Gastrointestinal toxicity contributes to dehydration and electrolyte losses, and occasionally anemia is severe enough to require transfusion. Salsalate produces less gastrointestinal injury than aspirin. Methyl salicylate can be very irritating, and salicylic acid keratolytic agents may produce oropharyngeal burns and more severe distal corrosive injury [23].

Asymptomatic elevation in serum transaminases may be noted in patients with chronic ingestion of salicylates, most commonly in patients with connective tissue diseases [24]. A few of these patients have abdominal pain, nausea, and jaundice. Although clinical evidence of meaningful hepatotoxicity is not typical of acute salicylate toxicity, investigators have reported a high prevalence of hepatic microvesicular steatosis in children who died as a result of salicylate poisoning [25]. Microvesicular steatosis, as a reflection of impaired fatty acid oxidation, can be secondary to mitochondrial dysfunction from numerous causes. In the outer mitochondrial membrane, however, salicylate also sequesters extramitochondrial coenzyme A, preventing the activation of fatty acids and fatty acid β oxidation.

Pulmonary Effects

Adult respiratory distress syndrome occasionally complicates acute salicylate toxicity but is more common in chronic salicylate toxicity [26, 27].

Cardiovascular Effects

Impaired myocardial ATP production and, to a lesser extent, acid–base disorders produce sinus tachycardia, despite correction of hypovolemia.

Heart failure and hypotension occur in seriously ill patients [28] but usually are not a problem until patients are near death. Ventricular arrhythmias, including sudden, unexpected ventricular fibrillation, and conduction disturbance including heart block are possible [29].

Effects on Coagulation and Platelets

Of all salicylate products, only aspirin significantly impairs platelet function. Salicylate (resulting from the ingestion of any product) inhibits the formation of vitamin K-dependent coagulation factors in a manner similar to that of warfarin (Coumadin), mainly by preventing the reduction of vitamin K quinone to the active hydroquinone [30]. Elevated prothrombin times usually occur 8–24 h after acute overdose and respond promptly to the administration of vitamin K₁. Despite coagulopathies and potential platelet dysfunction, hemorrhage remains a rare cause of serious morbidity or mortality in patients with salicylate toxicity, with the exception of occasional gastrointestinal bleeding.

Central Nervous System Effects

Given the large energy requirements of the brain, it is not surprising that neurotoxicity from impaired ATP formation may accompany salicylate toxicity. Agitation, combativeness, disorientation, confusion, and hallucinations characterize severe toxicity. Even more severe cases progress (sometimes rapidly) to convulsions, coma, respiratory depression, cerebral edema, and brain death [1, 28, 30–32].

Hill [33] showed in rats that elevated CNS salicylate concentration, leading to coma and seizures, was the most critical determinant of death, and this is consistent with clinical experience. Serious neurotoxicity, especially CNS depression or convulsions, carries a high mortality and commonly portends death in the next few minutes to hours. Even patients exhibiting shock and

hypotension almost always develop CNS dysfunction before life-threatening cardiovascular toxicity. CNS depression, disorientation, agitation, or convulsions always should be interpreted as an ominous sign when due to salicylate toxicity [28, 32–34].

Miscellaneous Effects

Hypocalcemia and hypercalcemia have been described as a component of serious salicylate toxicity [35, 36]. Rhabdomyolysis [37], commonly seen in any metabolic poisoning, may produce the typical complications, including disseminated intravascular coagulation, compartment syndromes, renal failure, hyperkalemia, and hypocalcemia. Acute tubular necrosis has been reported in the absence of rhabdomyolysis [38].

Tinnitus generally occurs when serum salicylate levels are greater than 20 mg/dL (>1.46 mmol/L). The patient may not complain of tinnitus, but instead simply may complain of difficulty in hearing. Auditory musical hallucinations also have been reported [39].

Significant hyperthermia is seen in only a few cases and is seen more commonly in patients who die, reflecting more severe toxicity [28]. Even comatose patients may have a normal temperature.

Finally, we have encountered two cases of severe poisoning (leading to coma) in which the administration of succinylcholine was followed immediately by diffuse rigidity and hyperthermia resistant to neuromuscular blockade. That both patients could have had familial malignant hyperthermia seems extremely unlikely. Rather, because ATP also is required for muscle relaxation, presumably low muscle ATP levels prevented relaxation after initial depolarization by succinylcholine. As in any poisoning characterized by low ATP levels (e.g., nitrophenol, fluoroacetate), rigor mortis may develop within a few minutes after death. We have noticed similar rigidity as a near-terminal finding on one occasion in which no succinylcholine was given.

Fig. 1 Salicylate exists in blood in an equilibrium between the ionized and un-ionized forms. HSAL, un-ionized salicylate; SAL^- , ionized salicylate

Pharmacokinetics

Pharmacokinetics of Salicylates

Volume of distribution: 0.15–0.35 L/kg or greater

Protein binding: 40–80%

Elimination: (1) mainly hepatic at low salicylate concentrations; (2) mainly renal at upper therapeutic and toxic serum salicylate concentrations

Active metabolites: none

Methods to enhance clearance: hemodialysis, alkaline diuresis

Absorption

During and after ingestion, all salicylate products are converted rapidly to salicylate. Salicylate impairs gastric emptying, and gastric bezoars have formed in patients with chronic ingestion of enteric-coated aspirin tablets [40]. We have seen salicylate concentrations increase for more than 24 h after large acute ingestions, although toxic levels commonly occur within 6 h. Enteric-coated and extended-release aspirin tablets may undergo delayed absorption, with nontoxic levels seen at

6 h despite serious ingestions [41, 42]. Liquid salicylate preparations (e.g., methyl salicylate, salicylic acid, pediatric aspirin products) undergo more rapid absorption than solid products. Toxic and fatal amounts of salicylate can be absorbed across the skin after the use of salicylic acid-containing keratolytic agents [2, 3, 43]. Of topical salicylate, 60% is absorbed across the psoriatic skin when covered with an occlusive dressing [43].

Distribution

About 40–80% of salicylate is bound to serum proteins, mainly albumin. As binding sites become saturated at high serum salicylate concentrations, the free, unbound fraction increases. Hypoalbuminemia, azotemia, and elevated serum salicylate levels all result in increased unbound serum salicylate concentrations [44–46]. The wide range of reported protein-bound fractions represents, to a large extent, variations in serum drug levels and albumin concentrations.

Salicylate exists in blood in an equilibrium between the ionized and un-ionized forms (Fig. 1). At physiologic pH, most salicylate resides in the ionized form. Only unbound, un-ionized salicylate readily crosses cell

membranes. Any condition that increases the unbound fraction (e.g., high serum salicylate concentrations, hypoalbuminemia) or increases the un-ionized fraction of salicylate (e.g., decrease in pH) increases salicylate's apparent volume of distribution. A decrease in pH can result in a movement of salicylate from the blood into the tissue, raising the tissue levels of salicylate and worsening systemic toxicity, while serum salicylate concentrations decline. A drop in pH of only 0.25 (e.g., 7.45–7.2) almost doubles the amount of un-ionized drug capable of diffusing into the tissue. In a healthy patient with low serum salicylate concentrations, the typical volume of distribution is about 0.16 L/kg. Salicylate's volume of distribution in the same patient with an elevated serum salicylate concentration and acidemia may reach 0.34 L/kg or greater [47].

The changing volume of distribution of salicylate makes interpretation of serum salicylate concentrations potentially misleading. Two patients with identical serum salicylate concentrations may differ markedly in the degree of toxicity because their tissue burden of salicylate may vary tremendously, depending on plasma albumin concentration, pH, and other factors that influence the volume of distribution for salicylate. Similarly, serum salicylate concentrations decline not only because of renal and hepatic elimination but also because a rise in the volume of distribution causes salicylate to leave the blood and enter the tissue, producing more severe toxicity. Patients may deteriorate and die as serum salicylate concentrations decrease [28, 31]. Similarly, it is important to treat the patient and not simply the serum salicylate concentration. This point is especially important in patients with chronic salicylate toxicity, who characteristically have a large volume of distribution and more severe toxicity for a given serum salicylate concentration.

Elimination

Salicylate undergoes hepatic metabolism, mainly by glucuronidation and by conjugation with glycine to form salicyluric acid (see Fig. 1) [48]. Both of these pathways become saturated within the range of therapeutic serum salicylate concentrations, leading to zero-order elimination kinetics

and an increasing role for renal elimination. During zero-order elimination kinetics, a set amount of drug is eliminated per unit time (not a set fraction of drug, as in first-order elimination), regardless of how much serum salicylate concentrations increase. The elimination “half-life” (a term that should not be used in zero-order kinetics) is changing constantly and increases as the serum salicylate concentration increases.

An increased fraction of unbound salicylate at high plasma concentrations also enhances renal clearance, making the kidneys the major route of elimination during salicylate toxicity [49]. Un-ionized salicylate undergoes reabsorption by renal tubules, prolonging elimination. Alkaline urine favors the formation of ionized salicylate, preventing reabsorption and enhancing secretion of un-ionized salicylate down its concentration gradient, both of which increase urinary elimination. The urinary clearance of salicylate can increase more than 500% by raising urine pH from 7.0 to 8.0 [50].

Saturable hepatic elimination kinetics, an increasing volume of distribution, dehydration, and aciduria act to prolong markedly the elimination of salicylate. In untreated or dehydrated patients with aciduria who have moderate-to-severe salicylate toxicity, more than 1–2 days may be required for serum salicylate concentrations to decrease by half, and prolonged absorption further attenuates the decline in serum salicylate levels.

A shift to zero-order elimination also allows serum salicylate concentrations to increase out of proportion to the daily dose. Doubling a daily aspirin intake may result in a threefold or fourfold increase in serum salicylate concentrations; this explains why chronic salicylate toxicity is produced with relatively small increases in salicylate doses.

Toxic Doses

The acute ingestion of 150 mg/kg of aspirin or an equivalent amount of another salicylate-containing product mainly produces gastrointestinal irritation and vomiting. Ingestion of

150–300 mg/kg of aspirin results in mild-to-moderate toxicity with abdominal pain, vomiting, dehydration, hyperpnea, tinnitus, and acid–base disturbances. Ingestion of more than 300 mg/kg of aspirin produces moderate-to-severe toxicity and death. Patients with medical conditions that predispose them to a large volume of distribution (e.g., renal failure, hypoalbuminemia, acidemia) and patients who have ingested salicylate previously within the last 12–24 h become more toxic for a given amount ingested.

Attempts to develop a nomogram of salicylate concentration against time have been unsuccessful in accurately predicting toxicity. Historically, the Done nomogram [51] was suggested to assist in determining the degree of toxicity after salicylate ingestion in children. A serum salicylate level drawn 6 h or more after ingestion could be plotted on the nomogram, and the patient could be placed at various degrees of toxicity. The Done nomogram can be misleading, however. The nomogram can overestimate and, most importantly, greatly underestimate the degree of toxicity. A person with a level in the “mild” range may still become severely ill hours later if acidemia or dehydration is not corrected or if salicylate levels continue to increase. The use of the Done nomogram is not recommended [52]. All symptomatic patients should be treated regardless of where their serum salicylate levels fall on a nomogram.

Clinical Presentation

Acute Salicylate Toxicity

Presenting complaints and findings after acute ingestion of a salicylate product include vomiting (sometimes with hematemesis), abdominal pain, tinnitus, tachypnea, hyperpnea, diaphoresis, tachycardia, dehydration, leukocytosis, and ketonuria (Table 3). If rhabdomyolysis is not present or severe and if dehydration has not limited potassium excretion, laboratory analysis in most patients reveals hypokalemia. Adults usually present with respiratory alkalosis with or without a mild metabolic acidosis and with alkalemia. Young children commonly present with acidemia.

Table 3 Clinical findings of salicylate toxicity

Gastrointestinal
Nausea, vomiting, abdominal pain
Gastrointestinal bleeding
Gastric perforation (rare)
Metabolic
Respiratory alkalosis
Metabolic acidosis
Ketosis
Hypokalemia
Hyperglycemia, normoglycemia, or hypoglycemia
Ketosis
Central nervous system
Confusion, agitation, combativeness, hallucinations
Seizures, coma, cerebral death
Cerebral edema
Low cerebrospinal fluid glucose (in animals)
Cardiovascular
Sinus tachycardia
Hypotension, ventricular arrhythmias
Shock, asystole
Pulmonary
Acute respiratory distress syndrome
Hematologic
Leukocytosis
Prolongation of prothrombin time
Miscellaneous
Diaphoresis
Hyperthermia
Rhabdomyolysis
Renal failure
Tinnitus, auditory hallucinations (e.g., musical)

Serum glucose concentrations usually are normal or elevated early in acute poisoning.

As the severity of poisoning progresses, worsening acidosis, worsening tachycardia, and diaphoresis appear, with progressive CNS dysfunction characterized by agitation, lethargy, confusion, combativeness, seizures, or coma. Metabolic acidosis is typically accompanied by an elevated anion gap. In many cases, however, laboratory interference causes salicylate to be misread as chloride, leading to a falsely low or negative anion gap [53, 54]. The absence of an elevated anion gap in a patient with clinical symptoms of salicylate toxicity should not deter pursuit of the diagnosis. Although young children are

more likely to develop hypoglycemia as glycogen stores are depleted, adults can develop hypoglycemia as well. Acute respiratory distress syndrome is more common in chronic salicylate poisoning but can occur in severe, acute poisonings. Elevated prothrombin times do not occur until hours after ingestion.

Patients who will die from acute salicylate poisoning usually exhibit CNS dysfunction and then die from refractory shock with terminal ventricular arrhythmias or asystole. Acidemia usually is present by this time, and the combination of tachycardia, diaphoresis, and CNS dysfunction, especially in the presence of acidemia, is an ominous indication of severe toxicity and great risk of deterioration and death if aggressive action is not taken immediately [28, 32–34]. Clinical deterioration can be rapid; patients who are awake and alert may die within 6 h [1]. Because of the increasing volume of distribution with higher salicylate concentrations and acidemia, patients may die, while serum salicylate concentrations are declining.

Chronic Salicylate Toxicity

Chronic salicylate toxicity is described best as a syndrome rather than as a specific dose over a particular time. A dehydrated and azotemic patient may develop chronic toxicity while taking doses that would not affect an otherwise healthy person.

Most patients with chronic salicylate toxicity are brought in by family members because of altered mental status characterized by lethargy, irritability, confusion, hallucinations (including auditory), seizures, or coma. Although dehydration is common, vomiting and abdominal pain usually are not major complaints. Tinnitus is common, and an elevated prothrombin time frequently is noted. Many patients are acidemic. Elevated hepatic transaminases are seen commonly in many patients using salicylate products regularly and are not specific for this syndrome. Tachypnea is common.

Leatherman and Schmitz [15] described invasive hemodynamic measurements in five selected hypotensive patients with chronic salicylate toxicity who exhibited low systemic vascular

resistance and cardiac outputs ranging from 5.1 to 8.5 L/min. How representative these hemodynamic findings are of all patients with salicylate toxicity, including patients without hypotension, is unknown.

Because of a large volume of distribution, patients with chronic salicylate toxicity appear sicker than acutely toxic patients with the same serum salicylate level. Patients taking carbonic anhydrase inhibitors and salicylate may develop serious salicylate toxicity [55, 56] at therapeutic or minimally elevated serum salicylate concentrations because carbonic anhydrase inhibitors alkalize cerebrospinal fluid while lowering blood pH [57, 58], both of which processes concentrate and trap salicylate within the CNS. Salicylate increases the unbound and active fraction of acetazolamide in blood [56], enhancing acetazolamide's effect on salicylate distribution.

Differences between acute and chronic salicylate toxicity are not always clear, but rather represent a progression of signs and symptoms. The longer a patient presents after an acute ingestion, the more he or she behaves like a patient presenting with chronic toxicity. Altered CNS function, elevated prothrombin times, and acidemia that characterize chronic salicylate toxicity also are typical of an acute overdose patient hours after ingestion.

Differential Diagnosis

The differential diagnosis for salicylate toxicity is large and includes many disorders that produce metabolic acidosis (with an increased anion gap in more ill patients), respiratory alkalosis, gastroenteritis, and CNS dysfunction. Examples include sepsis, Reye's syndrome, diabetic ketoacidosis, hepatic failure, and alcoholic ketoacidosis. Poisonings by theophylline, caffeine, ethylene glycol, methanol, iron, ethylene glycol ethers, and heavy metals may produce acidemia, gastrointestinal symptoms, coma, and convulsions. A generalized seizure from any cause (e.g., isoniazid, cocaine, meningitis) usually produces transient metabolic acidosis that resolves over 20–60 min after the seizure is terminated. Direct or indirect

β -adrenoceptor stimulation (e.g., bronchodilators, theophylline, sympathomimetics) produces tachycardia, metabolic acidosis, respiratory alkalosis, hypokalemia, hyperglycemia, leukocytosis, ketosis, and, depending on the agent (e.g., amphetamines, theophylline), convulsions. Diflunisal, a nonsteroidal antiinflammatory drug, does not produce salicylate toxicity but causes falsely elevated serum salicylate concentrations by some colorimetric laboratory methods [59].

Evaluation and Treatment

Special Airway and Ventilatory Considerations

Special considerations must be addressed when instituting sedation or mechanical ventilation. The administration of a sedative or narcotic to a patient poisoned with salicylate may decrease respirations, lessen respiratory alkalosis, and result in a prompt decrease in arterial pH from an unopposed metabolic acidosis. This situation may produce a prompt movement of salicylate into the brain with resultant clinical deterioration. A similar scenario occurs when a physician sedates or relaxes the patient for endotracheal intubation and then provides normal minute ventilation volumes with mechanical ventilation. Because of adverse hemodynamic effects and risks for barotrauma, aggressive mechanical hyperventilation should not be used to maintain pH in these settings, but rather the physician should recognize the probable consequences of sedation or controlled mechanical ventilation and should administer additional intravenous sodium bicarbonate to prevent dangerous decreases in arterial pH.

Decontamination and Initial Evaluation

Oral activated charcoal alone has been reported to be superior to induction of vomiting with ipecac syrup [60, 61]. Activated charcoal (e.g., 100 g) adsorbs salicylates and should be given to patients who have ingested potentially toxic doses of salicylate products, although no controlled trials in

poisoned patients have evaluated outcomes (level III evidence). Although repeated-dose oral activated charcoal has been claimed to be effective in shortening elimination half-life in a retrospective study [62], a prospective randomized study in human volunteers who ingested nontoxic doses of salicylate suggested that the routine use of repeated-dose charcoal might be without benefit [63]. If serum salicylate concentrations continue to increase after administration of activated charcoal, most toxicologists administer additional oral charcoal. Severe nausea and vomiting in an acutely poisoned patient may limit charcoal dosing.

In symptomatic patients, laboratory studies should include analysis of serum or plasma for electrolytes, blood urea nitrogen, glucose, creatine kinase, creatinine, prothrombin time, and salicylate concentration. Because of the ready availability of acetaminophen and frequency of acetaminophen overdose and because acetaminophen-containing products may have brand names that are similar to the names of products containing aspirin, serum acetaminophen concentration should be measured whenever salicylate toxicity is being considered. Urinalysis and complete blood count also should be obtained. Arterial blood gases should be measured to determine the type and degree of acid–base imbalance. A chest radiograph should be obtained on all moderately to severely ill patients or any patient with respiratory distress or hypoxemia.

A patient who appears ill from salicylate toxicity should be treated regardless of serum salicylate concentration. Most symptomatic patients have serum salicylate concentrations greater than 20 mg/dL (>1.46 mmol/L). Severe toxicity commonly accompanies serum salicylate concentrations greater than 70 mg/dL (>5.1 mmol/L). Severe toxicity and death can be seen at lower levels, however. Because of the variability in volume of distribution, serum salicylate concentrations in patients who die are, on average, similar to concentrations in patients who live. Chapman and Proudfoot [64] reported plasma salicylate concentrations ranging from 55 to 120 mg/dL (4.01–8.76 mmol/L) in fatal cases and ranging from 18 to 135 mg/dL (1.31–9.85 mmol/L) in survivors.

The acute ingestion of enteric-coated and extended-release salicylate may result in nontoxic serum salicylate concentrations for the first few hours after ingestion but high serum salicylate concentrations and severe toxicity later [41, 42]. Because of inaccurate histories provided from overdose victims or relatives and the delayed and prolonged absorption of enteric-coated products, anyone who may have ingested more than 150 mg/kg of enteric-coated aspirin should be admitted for observation and measurement of serial serum salicylate concentrations for 18–24 h.

Moderately to severely ill patients belong in the intensive care unit. The purpose of admitting relatively asymptomatic patients or patients with only mild symptoms is usually concern for possible clinical deterioration that can be rapid. Patients who are awake and alert can die within 6 h. This fact, along with the need for frequent vital signs and laboratory studies, means that almost all patients requiring admission for salicylate toxicity should be placed in an intensive care unit setting.

Supportive Treatment

All patients with an abnormal mental status or seizures should be presumed hypoglycemic and should receive appropriate doses of intravenous glucose, especially if bedside determinations of serum glucose levels are not immediately available. As with all drug-induced and toxin-induced seizures, benzodiazepines and barbiturates are the anticonvulsants of choice (level III evidence).

The average adult patient who presents several hours after an acute ingestion of salicylate with vomiting, perhaps tinnitus, and hyperventilation typically is dehydrated by 4–6 L or more. The insensible fluid losses from diaphoresis, hyperventilation, and third spacing into muscles undergoing rhabdomyolysis are frequently underestimated and limit initial attempts at rehydration and prevention of further negative fluid balances, which impairs salicylate elimination. Aggressive initial rehydration should be monitored carefully, and the treating intensivist must recognize that despite continuous intravenous

infusions of 500–600 mL/h, many patients continue to experience negative fluid balances with rising hematocrits and serum sodium concentrations that must be met with additional fluid boluses and increases in continuous infusion rates. These actions can be undertaken only with frequent bedside assessments and frequent laboratory studies. Frequent blood and urine collections are facilitated by indwelling arterial and urinary catheters.

After initial hydration, primary efforts should be directed at keeping arterial pH greater than 7.4 in symptomatic patients. A reasonable goal is an arterial pH of 7.5 to limit increases in volume of distribution and tissue (e.g., CNS) salicylate concentrations. A secondary goal of therapy is to alkalinize urine to enhance urinary salicylate excretion. The more alkaline the urine (up to a pH of approximately 8.0), the greater the excretion of salicylate. Intensivists must recognize that the main reason for alkalization is to elevate blood pH. Alkaluria, although desirable, is of secondary concern. Alkaluria seems to be more important than diuresis with regard to enhancing salicylate excretion [65].

Two important methods for sodium reabsorption in the renal distal and collecting tubules are tubular secretion of potassium ions and tubular secretion of hydrogen ions. Even during alkalemia and normokalemia, aciduria persists, impairing salicylate elimination, if the kidney is preferentially reabsorbing sodium by excreting hydrogen ions rather than potassium ions into the tubular lumen. Therefore, both bicarbonate and potassium supplementation are usually required to ensure alkaluria.

There are no randomized trials examining outcomes in patients treated with different infusion solutions. Based on experience, we initially rehydrate patients aggressively with either 0.9% sodium chloride or Ringer's lactate (if hyperkalemia is not present). In moderately to severely ill patients, we begin a continuous infusion of 1000 mL of 5% dextrose in water, to which is added 150 mEq of sodium bicarbonate and at least 50 mEq of potassium as potassium chloride at 250–300 mL/h, assuming the adequate urine output and the absence of hyperkalemia.

Additional simultaneous infusions of crystalloid (e.g., 5% dextrose in 45% sodium chloride) usually are required to maintain adequate hydration, and total infusion rates greater than 500 mL/h may be required in moderately to severely ill patients. A urinary output of 2–3 mL/kg/h is desirable. Hemoglobin concentrations and hematocrits are followed to detect occult gastrointestinal bleeding. Arterial blood gases, serum electrolytes, serum salicylate concentrations, and urine pH are measured every 2–4 h in moderately ill patients and at least every 1–2 h in severely ill patients to ensure the absence of acidemia and to detect disorders in serum potassium concentrations that may require adjustment in the electrolyte composition of the infusion solution. This monitoring also detects hyponatremia and hemoconcentration, which suggest insensible losses requiring further replacement. Serial (e.g., daily) serum creatine kinase activity is monitored to detect rhabdomyolysis.

Decreases in arterial pH from metabolic acidosis are treated with repeated intravenous boluses of 1–2 mEq/kg of sodium bicarbonate as needed. A decrease in urine pH less than 7.5–8 despite normokalemia is treated with additional potassium (intravenous or oral) as long as hyperkalemia is not present. After ensuring adequate hydration and urine flow, the potassium requirements in some patients with moderate-to-severe salicylate toxicity exceed 25 mEq/h to ensure alkaluria. We administer 10–15 mg of vitamin K₁ intravenously to all patients with moderate-to-severe toxicity because prothrombin times usually are elevated within several hours without such therapy, although there are no trials demonstrating a change in outcome (level III evidence).

If objective evidence of hypervolemia develops and there is no appropriate increase in urine flow, intravenous furosemide can be given. However, the most common cause of oliguria is hypovolemia. Pulmonary edema usually represents adult respiratory distress syndrome, not fluid overload.

In patients with renal failure and oliguria who require less than 200 mL/h to maintain good hydration, we commonly infuse crystalloid

solutions containing 10% dextrose to prevent neuroglycopenia, which in animals may occur despite normoglycemia. Carbonic anhydrase inhibitors, such as acetazolamide, are best not given to alkalinize urine because they also alkalinize cerebrospinal fluid [57, 58], trapping salicylate in the CNS – opposing the aforementioned goals of therapy.

Severe neurotoxicity, characterized by lethargy, agitation, confusion, seizures, coma, or continued deterioration in level of consciousness despite supportive care, is an ominous sign and an indication for immediate hemodialysis, even if serum salicylate concentrations have been declining yet remain greater than 20–40 mg/dL (>1.46–2.91 mmol/L). Some toxicologists also administer intravenous mannitol (0.25–0.5 g/kg) in an effort to reduce or prevent further worsening of cerebral edema in these patients (level III evidence).

Serum salicylate levels that have declined may rise again in a delayed manner from continued absorption after discontinuation of an alkaline diuresis [66]. Thus, serum salicylate levels should be rechecked in patients who have been significantly ill after bicarbonate infusions are halted to be sure drug concentrations are remaining low.

Hemodialysis

Salicylate's high water solubility, relatively low protein binding, small volume of distribution, and low molecular weight allow for effective removal by hemodialysis [67]. Hemodialysis is indicated for patients with one or more of the following: significant neurotoxicity (e.g., lethargy, agitation, coma, convulsions), renal failure, cardiovascular instability, and extremely elevated serum salicylate concentrations that are increasing despite hydration and attempts at alkaline diuresis. Others have recommended hemodialysis for pulmonary edema as well. On the one hand, previous recommendations that all patients with serum salicylate concentrations greater than 80–100 mg/dL (>5.84–7.3 mmol/L) must undergo hemodialysis immediately were too extreme because awake and alert patients with good blood pressure and urine

output who have a serum salicylate concentration of 105 mg/dL (7.66 mmol/L) that is known to be falling can do well with intensive medical therapy. On the other hand, successful treatment of these patients requires a great deal of physician time, frequent bedside evaluations, frequent laboratory studies, and often 2–3 days in the intensive care unit. Most patients with serum salicylate concentrations greater than 100 mg/dL (>7.3 mmol/L) eventually meet the criteria for hemodialysis (e.g., CNS dysfunction), even while serum salicylate concentrations decrease. Failure to institute hemodialysis promptly in deteriorating patients leads to unnecessary deaths [1, 64]. Mildly to moderately encephalopathic patients with chronic salicylate toxicity, in whom absorption has peaked, can do well with intensive medical therapy alone.

At our center, extraction ratios across the dialysis cartridge commonly range from 35% to 70% using double-lumen dialysis catheters and high-flux membranes with blood flow rates of 400 mL/min. In general, hemodialysis is performed until serum salicylate concentrations have decreased to less than 20 mg/dL (<1.46 mmol/L). Most patients with salicylate toxicity require 4–6 h of hemodialysis to achieve this goal. Because of prolonged absorption, some patients require more than 6 h of hemodialysis or require a repeat session of hemodialysis if salicylate levels increase again to produce serious toxicity.

Occult or minor gastrointestinal bleeding from the corrosive action of salicylate can become more severe and apparent when the patient is heparinized for hemodialysis, but this is uncommon. We routinely type and screen the patient for transfusion, however, when arranging for hemodialysis and monitor hemoglobin concentrations and hematocrit values more closely during and shortly after dialysis. Because clinically significant gastrointestinal bleeding during hemodialysis is uncommon, concern for gastrointestinal bleeding from salicylate rarely should be considered a contraindication for heparinization and hemodialysis for life-threatening salicylate toxicity. Blood volume can be supported with transfusions, if needed, whereas death from salicylate is possible and often probable without hemodialysis.

Charcoal hemoperfusion also removes salicylate well; however, hemodialysis has the valuable added advantage of immediately correcting electrolyte and acid–base balance without the potential adverse effects associated with hemoperfusion (e.g., thrombocytopenia, hypocalcemia) [64, 67]. Peritoneal dialysis is relatively ineffective at removing salicylate compared with hemodialysis and should be used only when hemodialysis is not an option.

Intensive Care Unit Discharge

Criteria for ICU Discharge in Salicylate Poisoning

Awake, alert, and no clinical evidence of toxicity

Serum salicylate concentrations <20 mg/dL (1.46 mmol/L) and known to be declining

Patients can be discharged from the intensive care unit when they are awake and alert and metabolically stable and when serum salicylate concentrations are less than 20 mg/dL (<1.46 mmol/L) and known to be decreasing.

Common Errors in the Management of Salicylate Poisoning

Underestimating the seriousness of salicylate toxicity

Failing to consider the diagnosis of chronic salicylate toxicity in elderly patients with altered mental status

Failing to recognize potential for delayed and continued absorption of salicylate for >24 h after overdose

Forgetting that coingestion of central nervous system depressants masks hyperventilation and respiratory alkalosis

Believing that most patients with salicylate poisoning are hyperthermic

(continued)

Confusing units of measurement for serum salicylate concentrations, which vary among laboratories (10 mg/dL = 100 mg/L)

Using the Done nomogram

Failing to recognize potential for clinical deterioration and death despite decreasing salicylate serum concentrations

Underestimating insensible fluid losses and allowing patients to become hypovolemic despite what may seem like liberal fluid administration

Failing to recognize that salicylate toxicity is commonly accompanied by falsely elevated serum chloride concentrations and resultant falsely low anion gaps

Focusing on alkalizing urine rather than alkalizing blood

Not giving required potassium supplementation to alkalize urine successfully

Failing to obtain and review laboratory studies frequently

Failing to institute hemodialysis at the onset of neurotoxicity

Allowing arterial pH to decrease with the use of sedatives or the institution of endotracheal intubation and mechanical ventilation

Giving furosemide to hypovolemic patients with pulmonary edema from adult respiratory distress syndrome

Failing to consider or monitor for hypoglycemia and rhabdomyolysis

3. Direct main efforts at correcting and maintaining euvoemia and keeping blood pH alkaline. Urinary alkalization usually requires sodium bicarbonate *and* potassium supplementation.

4. Bedside evaluations and laboratory studies (electrolytes, blood gases, salicylate concentrations, urine pH) every 1–2 h are required for patients with serious salicylate toxicity.

5. Decreases in pH and elevated serum salicylate levels result in an increase in volume of distribution, with a movement of salicylate from the blood into the brain and other tissues. Patients can deteriorate and die while serum salicylate concentrations are decreasing. Awake and alert patients can die within 6 h.

6. Monitor for and prevent decreases in arterial pH when giving sedatives/relaxants or controlling ventilation.

7. Hemodialysis should be instituted at the onset of neurotoxicity.

8. Pulmonary edema usually reflects adult respiratory distress syndrome.

9. Do not confuse units of measurement for serum salicylate concentrations, which vary among laboratories (10 mg/dL = 100 mg/L).

Key Points in the Management of Salicylate Poisoning

1. Salicylate absorption may continue for >24 h, and onset of absorption may be delayed with enteric-coated aspirin.
2. Patients with moderate-to-severe salicylate toxicity typically are 4–6 L dehydrated and may exhibit large maintenance fluid requirements because of insensible losses from hyperventilation, sweating, and vomiting.

Special Populations

Pregnant Patients

Salicylate crosses the placenta and concentrates in the fetus at higher serum levels than in the mother [68, 69]. The relative acidemia of the fetus also contributes to higher fetal *tissue* salicylate levels for already elevated fetal *serum* salicylate concentrations (large fetal volume of distribution). The fetus possesses less capacity to buffer acidemic stress imposed by salicylate and, compared with the mother, a reduced capacity to excrete the toxin. This situation collectively places the fetus at greater risk of death for a

given maternal serum salicylate concentration than the mother.

Because the fetus has greater toxicity than the mother, it seems wise to institute hemodialysis for lesser degrees of maternal toxicity than those in nonpregnant patients. Maternal hemodialysis can decrease placental blood flow. There are no studies to guide clinicians in deciding what maternal serum salicylate concentration crosses the threshold for hemodialysis. In a woman with a premature fetus, we institute hemodialysis for signs of fetal distress in the presence of maternal chronic salicylate toxicity or whenever maternal salicylate concentrations are greater than 40 mg/dL (>2.92 mmol/L) [70]. In a woman with a mature fetus, immediate delivery might allow more intensive care for the infant [71]. Alternatively, maternal hemodialysis might remove salicylate more safely and effectively from the fetus (through redistribution) than fetal therapies after delivery. In general, we lean toward hemodialysis in the latter situation because it is much easier to perform hemodialysis on the mother than on a newborn.

Chloroquine

Chloroquine is used to prevent and treat malaria in limited geographical areas (e.g., Central America and the Far East) and to manage immunological disorders such as systemic lupus erythematosus and rheumatoid arthritis. It represents the most severe and frequent cause of poisoning by any antimalarial drug. Chloroquine is a frequent method of suicide in Africa [1], France [2, 3], Asia, and the Pacific [3, 4]. In Zimbabwe, a marked association with pregnancy was reported as a result of the mistaken belief that it is an abortifacient [1]. The development of the Internet over the last 20 years or so has led to increased information about drugs and their toxic effects and has dramatically increased the availability of drugs illicitly. Evidence also demonstrates that suicidal people search the Internet to choose their drug(s) for suicide [5].

Among 167 chloroquine poisoning cases admitted to a toxicology critical care unit, the mortality was less than 10%; these are the best survival figures quoted in the literature to date [2]. The average fatal dose is 8 g, with the lowest reported fatal dose being 5 g [5]. An ingested dose of chloroquine of >5 g is a good predictor of fatality, with a specificity of 0.98 [3]. Messant et al. [6] describe survival in a patient ingesting 10 g. In some reported cases across the literature, death could have been avoided by appropriate medical care. Other readily available indices such as systolic blood pressure less than or equal

Fig. 1 Chemical structure of chloroquine

to 80 mmHg and QRS duration greater or equal to 120 msec on EKG are also used to indicate the need for ventilation, epinephrine, and diazepam clinically [7, 8]. Children ingestions of greater than 10 mg/Kg of chloroquine demand observation and monitoring for 4–6 h [9].

Chemistry and Pharmacology

The chemical name of chloroquine is 7-chloro-4-(4'-diethyl-amino-1'-methylbutylamino)-quinoline ($C_{18}H_{26}ClN_3$) (Fig. 1). Its molecular weight is 319.9, and it has pK_a values of 8.4 and 10.8. It is insoluble in water.

Chloroquine is absorbed readily from the gastrointestinal tract; the bioavailability is 78% for solution and 89% for tablets [10]. It accumulates in high concentrations in tissues such as the kidneys, liver, lungs, and spleen [10]. Chloroquine is bound strongly in melanin-containing cells, such as those in the eyes and retina. It has a low toxic/therapeutic margin, and care must be taken in prescription to prevent unintentional intoxication.

Pharmacokinetics of Chloroquine* [10]

Apparent volume of distribution: 116–285 L/kg

Protein binding: 50–65% in plasma

Mechanism of clearance: 61% urinary excretion

Active metabolite: desethylchloroquine

Terminal half-life:[†] 60 days

Methods to enhance clearance: none effective other than activated charcoal

*The half-life correlates well with peak plasma concentration; toxicokinetics is dose-dependent.

[†]Terminal half-life of desethylchloroquine is longer than the parent drug.

Pathophysiology of Toxic Effects

Cardiovascular toxicity of chloroquine is due to its quinidine-like (class Ia) actions. It inhibits spontaneous depolarization, slows conduction, lengthens the refractory period, and raises the electrical depolarization threshold. These actions cause depressed contractility, impaired conductivity, and decreased excitability but heighten the possibility of reentrant arrhythmias [11]. The pathophysiology of the effects of these sodium channel blocking agents is described in ► Chaps. 21, “Cardiac Conduction and Rate Disturbances,” and ► 39, “Sodium Channel-Blocking Antidysrhythmics.” Hypotension and shock are due to negative inotropic activity rather than peripheral vasodilation [12]. Neurologic symptoms of chloroquine are due to either direct central nervous system toxicity, which lowers the threshold for convulsions, or cerebral ischemia secondary to cardiovascular disturbances.

The mechanisms of hypokalemia have not been established, but its close temporal relationship with chloroquine toxicity suggests a potassium transport disturbance that favors transport of potassium into the cells and blockade of cardiac potassium channel human ether-a-go-go-related gene (HERG) [13, 14]. The data collected in the study by Clemessy and colleagues [14] do not support hypokalemia as a result of potassium depletion. Hypokalemia cannot be attributable to gastrointestinal losses because diarrhea is not common, and vomiting occurs in only about 30% of cases and is not prolonged. Urinary potassium wasting is not responsible because potassium losses in urine are low. Alkalosis is not the cause because most patients are acidotic [14].

Clinical Presentation and Life-Threatening Complications

Chloroquine overdoses usually have several characteristics in common. The interval between ingestion and onset of symptoms is short, and death, when it occurs, is often within 12 h. However, the risk of delayed death may persist up to 48 h, following the ingestion of high doses. At autopsy, common findings include cerebral and pulmonary edema. Tissue concentrations in a fatal overdose are shown in Table 1 [15]. The therapeutic plasma concentration is 1 mg/L (3.1 $\mu\text{mol/L}$) [16]. Plasma values reflect only a small proportion of total body chloroquine load because its apparent volume of distribution is high 10. The mortality rate in published studies is 12–35% and is among the highest in clinical toxicology [17]. Symptoms of chloroquine overdose usually start within 1–3 h of ingestion and include nausea, vomiting, agitation, drowsiness, hypokalemia, headaches, and visual disturbances [18]. After large ingestions, rigidity, coma, convulsions, hypotension, and arrhythmias occur.

Cardiovascular

In severe poisoning, cardiovascular signs promptly follow the appearance of the initial symptoms [17]. Cardiac arrest can be the first sign of overdose, however [12]. Systemic hypotension is one of the most frequent signs of chloroquine poisoning and without appropriate therapy may progress rapidly to cardiogenic shock with increased central venous pressure.

EKG abnormalities include modifications of repolarization with prolonged QT_c or QRS interval, increased U waves, and depression of the ST-T segment and flattened or inverted T waves. Intraventricular conduction delay and QRS widening are common. Atrioventricular block is less common. Ventricular tachycardia or fibrillation is observed early in chloroquine poisoning, and cardiac arrests tend to occur during the first hours. Ventricular extrasystoles and torsades de pointes may occur after 8 h. Delayed cardiac arrest (after 8 h) has been reported secondary to ventricular arrhythmias. A case of inverted Takotsubo cardiomyopathy (diagnosed by echocardiography) has

Table 1 Chloroquine concentrations in a fatal case

Specimen	Concentration
Blood	33 mg/L (103 $\mu\text{mol/L}$)
Kidney	110 mg/kg (344 $\mu\text{mol/kg}$)
Liver	169 mg/kg (528 $\mu\text{mol/kg}$)
Lung	73 mg/kg (228 $\mu\text{mol/kg}$)
Urine (antemortem)	367 mg/L (1147 $\mu\text{mol/kg}$)

From Ref. [15]

been reported in a 35-year-old female following ingestion of 7 g chloroquine – the pathophysiology of this remains uncertain [19].

Respiratory

Tachypnea is common in chloroquine poisoning. Apnea may occur suddenly, especially when convulsions start [20].

Central Nervous System

Neurologic effects appear rapidly after ingestion and include central nervous system depression and visual disturbances, such as blurred vision, diplopia, photophobia, and sometimes blindness. Blindness in acute chloroquine poisoning is transient and resolves without sequelae, in contrast to acute quinine poisoning or long-term chloroquine-induced retinopathy. Coma is less common and tends to be associated with circulatory failure, although cases with cerebral edema have been described [20]. Central nervous system excitation with agitation and seizures usually precedes cardiac arrest.

Myopathy and Neuropathy

Chloroquine overdose can cause a painless proximal myopathy with normal or slight elevation of creatine kinase in plasma. It can also be associated with a peripheral neuropathy [21].

Hypokalemia

Hypokalemia in chloroquine poisoning has been recognized since the 1980s. It is almost always present in severe chloroquine intoxication [20] and tends to appear within 3 h of ingestion. In one series stratified by severity, mild, moderate, and severe intoxications were associated with mean serum potassium concentrations of 3.5, 3.26, and 3 mmol/L, respectively [18]. Potassium

administration may lead to sudden hyperkalemia as chloroquine is eliminated, and rapid rigorous correction of early hypokalemia is not recommended [14].

Diagnosis

In the first 12 h after overdose, serum chloroquine concentrations correlate well with severity of intoxication, with severe effects being seen when serum concentrations are greater than 5 mg/L (15.5 μ mol/L) [18]. Mild intoxication without clinical symptoms is associated with serum concentrations less than 2.5 mg/L (7.8 μ mol/L). High serum chloroquine concentrations have been reported for 8–10 days, however, whereas clinical symptoms have resolved after 2 days [20]. Recent data demonstrates that blood concentrations are a better predictor of poisoning severity than plasma concentrations [8]. No patient with a blood chloroquine concentration of less than or equal to 6.7 mg/L (16 μ mol/L) had significant cardiovascular events. None with peak blood concentration of less than 10.5 mg/L (25 μ mol/L) had cardiac arrest or died [8]. The lowest reported blood concentration associated with a fatal outcome due to discontinuation of the epinephrine infusion was 6.5 mg/L, but up to 53 mg/L in blood and 7.0 mg/L in plasma survival is possible with meticulous supportive care [8]. However, blood or serum chloroquine concentrations are not routinely available in the majority of hospitals. In general, serum chloroquine concentrations are not needed to make the diagnosis or guide therapy.

Treatment

General Considerations

Although a human volunteer study has indicated that activated charcoal given within 1 h of ingestion decreases chloroquine absorption [22], it is unknown if such therapy alters the outcome of seriously poisoned patients. There is concern about patients developing seizures or altered mental status while taking activated charcoal, which

may lead to aspiration. Intubated patients who ingested more than 15 mg/kg of chloroquine and who present within the first hour can safely be given activated charcoal.

The use of antiarrhythmic agents should be avoided if possible because this may precipitate further arrhythmias by additional negative inotropic or chronotropic activity. Overdrive pacing is the treatment of choice (level IV evidence – clinical experience) for ventricular tachycardia or torsades de pointes [20]. Positive inotropic support, e.g., with epinephrine (adrenaline), may be required [20]. Plasma potassium must be monitored. Hypokalemia may have a protective effect and should not be corrected aggressively in the early stages of poisoning (level III evidence) [14]. If hypokalemia persists longer than 8 h, potassium should be replaced but cautiously, because rebound hyperkalemia often occurs during the recovery phase [14]. High-dose diazepam (2 mg/kg intravenously over 30 min followed by 2 mg/kg/day) may have a protective effect in chloroquine poisoning (level IV evidence), but respiratory support should obviously be present before it is given [20]. Early and continuous cardiorespiratory and neurologic support of these patients is crucial to their survival. The role of therapeutic hypothermia postarrest in chloroquine poisoning remains to be evaluated.

Indications for ICU Admission in Chloroquine Poisoning

ICU admission is dictated by clinical need and country- and hospital-specific policy. In some countries with greater availability of HDU/ICU facilities, any patient with >2 g chloroquine is admitted for meticulous observation and monitoring. In many countries, the following severe complications are indicators for ICU admission.

Cerebral edema
Pulmonary edema
Coma
Persistent seizures
Ventricular arrhythmias
Hypotension (systolic <80 mmHg)
QRS > or equal to 120 msec on EKG

Special Airway and Ventilatory Considerations

It is essential to intubate and ventilate patients early in chloroquine poisoning if arrhythmias, QRS prolongation, or hypotension is present. Based on Riou's study [24], endotracheal intubation and diazepam and epinephrine infusion are recommended for patients presenting with one or more of the following signs:

- Presumed ingested dose >4 g
- Systolic blood pressure >100 mmHg
- QRS length >100 msec

In the absence of any of those signs, cardiovascular monitoring (in the ICU during about 24 h) is sufficient.

Similarly, early intubation is advised if central nervous system features, such as recurrent seizures or coma, occur, especially if the use of high-dose diazepam is contemplated.

Role of Diazepam in Chloroquine Poisoning

Diazepam (0.1–0.3 mg/kg) given by slow intravenous injection, repeated as necessary, is effective at controlling convulsions [20]. In addition, diazepam at approximately 10 times higher doses has been reported to have a specific cardioprotective action in severe chloroquine poisoning [20]. Crouzette and coworkers [23] subsequently reported that diazepam reduces mortality in rats acutely poisoned with chloroquine, whereas Riou and colleagues [24] showed cardioprotection and increased urinary chloroquine excretion in chloroquine-poisoned pigs after treatment with diazepam.

Diazepam (2 mg/kg intravenously over 30 min) together with early mechanical ventilation and intravenous epinephrine (0.25 µg/kg/min and increased until systolic blood pressure was >100 mmHg) for 4 days was used to treat 11 patients with severe chloroquine poisoning. All of these patients would have been expected to die on the basis of historical control data. Ten of these 11 patients survived. Mechanical ventilation was instituted in part because of the respiratory depressant effect of high-dose diazepam.

The mechanism of the cardioprotective effect of diazepam in acute chloroquine poisoning is unknown. Croes and coworkers [25] reported a patient with severe chloroquine poisoning who also had ingested clorazepate (initial whole-blood chloroquine and plasma nordiazepam [a clorazepate metabolite] concentrations 7.9 mg/L [24.7 µmol/L] and 2.3 mg/L [8.4 µmol/L], respectively) and in whom mechanical ventilation was instituted. The patient was treated successfully with diazepam (2 mg/kg over 30 min, followed by 1–2 mg/kg over 24 h) and norepinephrine (0.25 µg/kg/min for 18 h). Despite plasma diazepam and nordiazepam concentrations of equal to or greater than 3 mg/L (10 µmol/L) (therapeutic level is 2 mg/L), however, the patient required additional sedation with piritramide to facilitate mechanical ventilation [25]. Although it is possible that chloroquine antagonized the sedative effects of diazepam, the patient may have acquired tolerance to these effects because of prior use of clorazepate. A study in animals suggested that barbiturate anesthesia and isoprenaline (isoproterenol) infusion may be a more effective combination than diazepam and epinephrine in treating severe chloroquine poisoning [26].

Cardiotoxicity

Studies in animals and humans suggested that early aggressive management of severe chloroquine intoxication has a cardioprotective effect and reduces the fatality rate [2, 24]. Hypotension should be managed initially with intravenous fluids. Epinephrine (1–5 µg/kg/min) may be necessary for hypotension that is nonresponsive to an intravenous fluid bolus. The epinephrine infusion rate is a good guide to poisoning severity for chloroquine, with the proviso that the ingested dose can be reliably obtained [7]. A threshold value of >3 mg/h (%) was the indicator for extreme poisoning severity [7].

Sodium bicarbonate intravenously is considered the treatment of choice for arrhythmias and should be used in patients with widened QRS and QT_c intervals (1–2 mL/kg of 8.4% sodium bicarbonate repeated if necessary, aiming for a pH of

7.45–7.5). There are no randomized controlled trials of efficacy of sodium bicarbonate in chloroquine poisoning, but its use now is recommended widely (level III and level IV evidences, respectively) [2, 27]. Its use has rationale, given the quinidine-like action of the drug and the efficacy of sodium bicarbonate in reversing similarly induced cardiovascular effects in poisoning by tricyclic antidepressants [1, 27, 28]. It also may reverse the cardiotoxic effects of hyperkalemia [29]. The treatment of choice for ventricular tachycardia and torsades de pointes is overdrive pacing [20]. All antiarrhythmic drugs are potentially arrhythmogenic and should be avoided. Class I agents in particular are contraindicated, and lidocaine should not be used because it may precipitate convulsions [2, 27].

The role of intravenous lipid emulsion (ILE) in chloroquine poisoning is controversial but theoretically beneficial given the lipophilic nature of chloroquine (lipid aqueous partition coefficient log P4.3). No benefit was found in one chloroquine case, when ILE was given 11 h post-ingestion [30]. A subsequent case was reported of a 24-year-old who was estimated to have ingested 14.5 g of chloroquine, together with 150 mg midazolam, 50 mg domperidon, and 40 mg ondansetron at an unknown time prior to admission. He initially developed a junctional rhythm with a blood pressure of 70/40 mmHg and then ventricular fibrillation and subsequent pulseless electrical activity (PEA) [31]. A bolus of 20% intralipid was given to the patient (1.5 ml/Kg followed by a continuous infusion of 0.25 ml/kg/min) and the PEA converted to a shockable rhythm, and a DC shock of 200 J was administered with transient reversion to sinus rhythm with a blood pressure of 120/90 mmHg [31]. This patient did not survive probably due to prolonged resuscitation, but the case raises the intriguing possibility of a role for ILE rescue therapy in life-threatening ventricular arrhythmias due to chloroquine. A discussion of the clinical pharmacology of ILE can be found in ► Chap. 3, “Therapeutic Approach to the Critically Poisoned Patient.”

Hypokalemia

Exogenously administered potassium has an effect on the heart similar to quinidine-like drugs in that it depresses excitability, slows the rate of depolarization, and decreases conduction [29]. The slowed depolarization and increased refractory period favor reentrant tachycardia. It is therefore recommended to avoid potassium replacement in the early hours of chloroquine intoxication, especially when cardiovascular effects are present [20]. In the second phase of poisoning, when ventricular extrasystoles and torsades de pointes are present, administration of potassium may be helpful, but it must be given cautiously to avoid sudden hyperkalemia. The best recommendation to date is to give patients with hypokalemia of less than 2 mmol/L no more than the equivalent of 160 mmol of K^+ per 24 h for an adult (level IV evidence) [14]. Lesser degrees of hypokalemia may be treated with 80 mmol of K^+ per 24 h for an adult (level IV evidence) [14]. The rationale for this relatively conservative therapy is that there is no total body deficit of potassium, and because the hypokalemia is due to a transport problem, it is difficult to correct. Although there is a correlation between the degree of hypokalemia and death, in most cases hypokalemia is not the direct cause of death [14]. As the intoxication resolves, there is serious documented risk of hyperkalemia [14].

Extracorporeal Removal Techniques

Hemofiltration, hemodialysis, and hemoperfusion have no role in the management of chloroquine poisoning because of the large volume of distribution and relatively high protein binding (see Table 1) [10].

Extracorporeal Membrane Oxygenation Treatment (ECMO)

The therapeutic intent of ECMO is to provide a “bridge to recovery” [32]. There are no randomized controlled trials of ECMO in poisoned patients with shock or ARDS [32]. Most case reports or series suffer from publication bias, i.e., more likely to be reported/published if outcome is successful. Vanzetto and colleagues [33] and Riou et al. (1988) [3] report successful outcome of VA-ECMO in patients with (hydroxy)/chloroquine overdose.

Relative contraindications to ECMO include advanced age, severe irreversible brain injury, untreatable metastatic cancer, severe organ dysfunction (e.g., Sequential Organ Failure Assessment score >15), and high-pressure positive ventilation for more than 7 days [32]. There is one absolute contraindication to ECMO: uncontrolled coagulopathy [32]. Patients require anticoagulation to avoid clots in the ECMO circuit. Complications include bleeding at the cannulation site (VV-ECMO) or surgical entry site (VA-ECMO), and the daily estimated blood transfusion requirement is approx 275 ml/day [32], and in contrast (where anticoagulation is not sufficient) embolic phenomena occur. Use of ECMO in experienced centers is associated with better clinical outcomes [34–36]. A detailed discussion of the use of ECMO can be found in ► Chap. 4, “Extracorporeal Membrane Oxygenation and Cardiopulmonary Bypass in the Poisoned Patient.”

Criteria for ICU Discharge in Chloroquine Poisoning

Resolution of cerebral edema
Resolution of pulmonary edema
Resolution of coma
Resolution of persistent seizures
Resolution of ventricular arrhythmias
Resolution of QRS prolongation

Special Populations

Elderly patients and patients with preexisting cardiovascular disease are likely to be more susceptible to the cardiotoxicity of chloroquine.

Key Points in the Management of Chloroquine Poisoning

1. The interval between ingestion and clinical signs is usually short (1–3 h).
2. The main risks are cardiovascular and central nervous system effects.
3. Early aggressive therapy is needed. The dose of epinephrine required to support the patient indicates the severity of poisoning.

4. Use diazepam combined with a positive inotrope such as epinephrine for severe chloroquine poisoning.
5. Chloroquine level in blood is not necessary for management – clinical features are more important.
6. Correcting hypokalemia early worsens cardiovascular toxicity.
7. Treating arrhythmias with antiarrhythmic drugs may result in negative inotropic and chronotropic effects, and cardiovascular status worsens.
8. Treating with high-dose diazepam without recognizing the need for ventilation may result in pulmonary aspiration.

Quinine

Quinine is an alkaloid extracted from the bark of various species of cinchona tree (*Rubiaceae*). It first was employed as an antipyretic, albeit not a very effective one, by the Portuguese in the first half of the seventeenth century.

Quinine salts are used in the treatment of chloroquine-resistant malaria. It also commonly is employed for the treatment of nocturnal cramps, for which it has limited efficacy [37]. Quinine has been used as an illegal abortifacient [38]. Quinine also has been used “to cut” street heroin [39]. It is used widely in tonic water for its bitter taste, and there are several case reports of allergic reactions when it has been consumed this way [40]. Detailed review of overdoses in Scotland showed that 64% of overdoses occurred with prescriptions for other family members, and in only 36% of cases had patients taken their own quinine [41].

Chemistry and Pharmacology

The chemical name of quinine is 6-methoxy- α -(5-vinyl-2-quinudindinyl)-4-quinoline-methanol ($C_{20}H_{24}N_2O_2 \cdot 3H_2O$) (Fig. 2). It is the *d*-isomer of quinidine. Its molecular weight is 378.5, pK_a values are 4.1 and 8.5, and it has low solubility in water. Quinine is absorbed rapidly

Fig. 2 Chemical structure of quinine

and almost completely from the gastrointestinal tract when given orally, with peak plasma concentrations occurring 1–3 h after ingestion [20].

Pharmacokinetics of Quinine [42]

Apparent volume of distribution: 2.1–3.1 L/kg.

Protein binding: 70–89%.

Clearance rate: 0.22–0.29 mL/min/kg*.

Elimination half-life: 26.5 ± 5.8 h at toxic levels.

Active metabolites: the liver, kidneys, and muscles metabolize 80% of ingested dose[†].

Methods to enhance clearance: multiple-dose activated charcoal is effective.

*20% is excreted unchanged in urine.

[†]Quinine is metabolized by P-450 CYP3A4; there is interindividual variance in expression of this coenzyme.

Pathophysiology

Toxicity of quinine can be divided into effects that are immunologically induced, such as purpura and skin rashes, and effects that are direct toxic actions, such as cardiotoxicity and ocular toxicity. Quinine has sodium channel blocking or local anesthetic actions but also is an irritant. The latter effects may be responsible for nausea in clinical use. The actions on cardiac muscle are class IA antiarrhythmic. It produces sodium channel blockade with moderate phase 0 depression, resulting in slowed conduction and repolarization.

The effects on cardiac muscle include an increased threshold in atrial, ventricular, and Purkinje fibers. As a result, the rate of Purkinje cell firing is decreased, and conduction velocity is decreased in ventricular muscle. The refractory period of cardiac muscle is increased. In the pacemaker cells of the sinoatrial node, spontaneous depolarization is inhibited, and this phenomenon extends particularly to the site of ectopic pacemaker activity. In larger doses, quinine causes atrioventricular beat generation (i.e., R-on-T phenomenon) because of its effects on ventricular refractory periods. When higher doses are used, ventricular fibrillation may supervene. The pathophysiology of sodium channel blockade effects on the myocardium is described in detail in ► Chaps. 21, “Cardiac Conduction and Rate Disturbances,” and ► 39, “Sodium Channel-Blocking Antidysrhythmics.” There is a direct myocardial depressant effect of quinine on cardiac muscle in addition to the sodium channel blockade. Quinine is a vasodilator, probably owing to its α -blocking activity [43].

Quinine has an oxytocic action on the uterus, which becomes more pronounced as pregnancy progresses. The exact mechanisms for this action are poorly understood. In skeletal muscle, quinine has a curare-like effect, reducing end motor plate excitability. Its use is known to cause deterioration in patients with myasthenia gravis [43]. Quinine probably does not have an effect on gastric smooth muscle. The emetic effect is likely due to a central action on the chemoreceptor trigger zone [43].

Quinine has been reported to stimulate insulin release in patients receiving treatment for falciparum malaria and causes hypoglycemia [44]. The mechanism of quinine-induced insulin release is a sulfonylurea-like suppression of potassium efflux, leading to β cell membrane depolarization and release of insulin and proinsulin from secretory granules in response to calcium influx via voltage-gated calcium channels.

Quinine has toxic effects that can result in blindness [45, 46]. This effect was postulated to be due to retinal arteriole vasoconstriction, but quinine has a direct toxic effect on retinal photoreceptor cells [45, 47]. There are no reports of retinal vascular changes being observed before

the onset of severe peripheral field constriction or blindness [48]. Normal arteriolar caliber has been observed with fluorescein angiography in a blind patient, and electroretinographic and electrooculographic studies performed soon after patients became blind all showed that the primary disturbance was in retinal function rather than impaired blood flow [46, 48]. Photoreceptor cells are affected first, followed by the ganglion layer and possibly the pigment epithelium [46, 48]. Visual evoked responses show abnormal waveform and prolonged latency from 3 days after poisoning to several months later, implying some damage to the nerve fiber, the retina, or both [49, 50].

Quinine has direct toxicity on the auditory nerve. Audiometry reveals bilateral nerve deafness due to inhibition of the transducing outer hair cells of the organ of Corti [51]. The decreased acuity is not usually clinically apparent, although the patient recognizes tinnitus [51]. Auditory toxicity is reversible.

Clinical Presentation and Life-Threatening Complications

Many clinical effects are common to an acute single overdose in self-poisoning and accumulation of quinine during therapy for malaria. These effects are known as *cinchonism* and include auditory symptoms, gastrointestinal disturbances, vasodilation, sweating, and headache [43]. As concentrations become greater, visual disturbance (plasma concentration >10 mg/L [31 $\mu\text{mol/L}$]) followed by cardiac and neurologic features (plasma concentration >15 mg/L [46 $\mu\text{mol/L}$]) occurs [52]. Similar levels in individuals who are ill with malaria do not result in toxicity owing to reduced free quinine present as a consequence of increased binding to α_1 acid glycoprotein. No clear fatal concentrations of quinine have been identified however, and the patient with the highest plasma concentration of quinine at presentation in one series (20.4 mg/L [63 $\mu\text{mol/L}$]) survived with retinal damage. The usual approximate fatal dose of quinine in an adult is approximately 8 g [53], but the smallest reported fatal dose in an adult was 1.5 g

[54–56]. AAPCC TESS reported no fatal quinine exposures in children under 6 years from 1983 to 2002 [56].

Cardiovascular

Vasodilation [53] and sweating are common. Mild systemic hypotension can occur in the absence of disturbance of cardiac rhythm due to dose-related depression of myocardial contractility. Cardiotoxicity of quinine is the predominant cause of death in overdose patients and the ultimate predictor of outcome. These features usually occur within 8 h of ingestion, although one case report claimed that torsades de pointes occurred 25 h after ingestion [57]. Electrocardiographic changes include prolonged PR, QRS, and QT_c intervals; ST segment changes and T wave changes; and the appearance of U waves [49]. EKG changes are common in overdose of >5 g in adults [55]. A large overdose often sees progressive PR and QRS interval widening, bundle branch block, and then sinus and atrioventricular blocks accompanied by bradycardia, followed by ventricular escape rhythms that may then yield asystole [56]. After large overdoses, broad-complex tachycardias, such as torsades de pointes, ventricular tachycardia, and ventricular fibrillation, may be seen [20].

Pulmonary

A 17-year-old man took 5 g of quinine bisulfate and presented 3.5 h later with deafness. He collapsed shortly after with broad-complex tachycardia. He had pulmonary edema and infection with *Pseudomonas* and *Staphylococcus*. His highest blood level of quinine was 17.8 mg/L (55 $\mu\text{mol/L}$). Autopsy revealed adult respiratory distress syndrome, but whether it was due to direct toxicity of quinine or due to severity of illness in the patient is unknown. Adult respiratory distress syndrome is not widely reported in patients seriously poisoned with quinine [58].

Gastrointestinal Tract

Mild nausea may be the only symptom in therapeutic doses. Profuse vomiting, epigastric pain, and diarrhea characterize large overdoses, however [43]. These symptoms are due to direct

irritant action on the gastrointestinal tract and central effects on the chemoreceptor trigger zone [43].

Hematologic

Quinine is a well-recognized cause of drug-induced thrombocytopenia and purpura [59]. The amounts needed are small, and these complications have been documented even after consumption of soft drinks containing quinine [43]. Agranulocytosis also has been reported [60]. In patients with malaria due to *Plasmodium falciparum*, anemia and intravascular hemolysis with renal failure are recognized complications. Attacks are reported to follow irregular quinine use.

Renal

Intravascular hemolysis can precipitate oliguria and acute renal failure. Notelovitz [61] reported a case of a 21-year-old woman who ingested 90 g of quinine during her 8th week of pregnancy. The patient subsequently became drowsy with dark red urine, which was positive for blood and protein. The patient became oliguric, and urea levels increased to 2080 g/L. The patient was treated with blood transfusion and hemodialysis and was discharged within 72 h.

Auditory

Tinnitus is common, and with large overdoses, the patient may be deaf [43]. Vertigo also can occur [43]. The auditory symptoms nearly always resolve within a few days of the overdose. There have been no cases reported of permanent deafness as a result of quinine overdosage.

Ocular

In quinine overdose, ocular toxicity depends on plasma concentration and often develops 6–15 h after the overdose but may be delayed for 1 or more days [49, 52]. The first symptoms are blurring of vision and disturbance of color perception; this can occur during quinine accumulation in antimalarial therapy. After acute overdose, however, more severe disturbances may occur with progressive constriction of the visual fields, reduced central acuity, and finally complete blindness. Many years after quinine-induced

blindness, retinal pigment degeneration still may be apparent, giving the appearance of retinitis pigmentosa.

The fundus appears normal when visual symptoms begin. The pupils may be fixed and dilated some time before light perception is lost, particularly if the patient has marked tunnel vision. Thereafter, there may be progressive constriction of retinal arterioles, a cherry-red macular spot, and macular edema; several days or weeks after the overdose, optic atrophy appears [62]. There are, however, reports of entirely normal fundoscopic appearances after the onset of blindness and of normal retinal artery appearances after blindness has developed [50, 63]. Many patients recover completely, although a significant number are rendered permanently blind. In general, the quicker the onset of recovery, the lower the degree of permanent impairment [49]. Of 30 overdose patients in a Scottish study, 8 had documented evidence of visual impairment, of whom 6 had visual problems at 32 months [41]. Fixed dilated pupils strongly suggest blindness due to quinine. Disk pallor does not indicate that permanent blindness will result [63–65].

Central Nervous System

Headache, confusion, and vertigo can occur [20]. Ataxia can occur after moderate overdose [20, 64]. After massive overdoses, convulsions, coma, and respiratory depression occur and have high associated cardiovascular mortality [20]. A case of “myeloopticoneuropathy” after quinine poisoning has been reported, but this case most likely represents vitamin B₁₂ deficiency and alcoholic neuropathy [65].

Hypoglycemia

Hypoglycemia is thought to be due to quinine-stimulated insulin release and can be a severe problem [66].

Diagnosis

All patients should have a 12-lead electrocardiogram, and plasma should be assayed for urea and electrolytes and glucose because quinine can cause

hypokalemia and hypoglycemia. Quinine can be assayed in plasma by immunoassay, and there is a correlation between plasma concentration and clinical features. Usually levels less than 10 mg/L (31 $\mu\text{mol/L}$) within 10 h of ingestion are not associated with clinically significant poisoning [56, 67]. Quinine concentrations are not performed routinely in the management of quinine-poisoned patients because knowledge of concentrations does not alter the patient's management.

Along with methanol, quinine should be considered in the differential diagnosis of patients presenting with acute bilateral blindness. The two can be differentiated easily because patients with methanol toxicity have a high anion gap acidosis and a positive methanol assay. Ergot derivatives, lead, and mercuric chloride are less common causes of blindness secondary to poisoning.

Treatment

General Considerations

Maintenance of the airway, breathing, and ventilation is crucial. If respiratory failure with or without pulmonary edema occurs, positive-pressure ventilation may be required. Intensive supportive therapy should be the mainstay of treatment, with meticulous correction of electrolyte abnormalities and any hypoxia. As with chloroquine, it is theoretically likely that mild hypokalemia protects the myocardium from the effects of quinine, so zealous overcorrection of hypokalemia is not advised. The guidelines provided earlier for chloroquine reasonably may be applied to the management of hypokalemia in quinine poisoning as well. Blood glucose concentrations should be monitored.

Multiple-dose activated charcoal (see ► Chap. 3, "Therapeutic Approach to the Critically Poisoned Patient") should be given to all patients who may have ingested greater than 15 mg/kg of quinine. The justification for this approach comes from the study of Prescott and colleagues [67], which showed that after treatment with repeated oral charcoal, plasma quinine concentrations decreased rapidly with a mean half-life of 8.1 ± 1.1 h compared with more than 24 h in a report of similarly poisoned patients. The visual impairment, which was expected in a

patient with cardiotoxicity and a plasma quinine concentration of 12.6 mg/L (39 $\mu\text{mol/L}$), did not occur. Repeated doses of oral charcoal have been shown to increase the rate of elimination of a therapeutic dose of quinine in healthy volunteers [68]. In another study [49], the rate of spontaneous quinine elimination was much slower, pointing to a dose-dependent metabolism of quinine [67]. Activated charcoal remains the only practical means of enhancing removal of this drug after overdose. The effect is not due so much to interference with absorption as it is to concentration-dependent diffusion of drug from the circulation to the gastrointestinal lumen, where it is bound irreversibly by charcoal [69]. Activated charcoal usually is given in repeated doses until the patient improves clinically (i.e., cardiotoxicity has settled, ocular toxicity is improving). Caution must be exercised, however, if the patient is not intubated and has an alteration in mental status. Such patients are at risk of aspiration, and thus activated charcoal should not be administered under those circumstances. It is not possible to show from the literature to date that treatment with charcoal enhanced the outcome of these patients [67].

Indications for ICU Admission in Quinine Poisoning

Admission to the ICU is common worldwide, given the risks of cardiovascular complications, and in most countries occurs on the basis of a high ingested dose, even if asymptomatic. The following severe complications are key indicators for ICU admission.

Persistent systemic hypotension
QRS elongation >120 msec or ventricular arrhythmias
Significant intravascular hemolysis
Convulsions
Coma
Persistent hypoglycemia

All patients with quinine overdoses should be placed on a cardiac monitor. Antiemetics may be given if vomiting is prolonged and severe, but

theoretically agents with cardiotoxic or neurotoxic actions should be avoided (e.g., antihistamines). Intravenous fluids and electrolyte replacement are necessary in cases with profuse vomiting or diarrhea.

Cardiotoxicity

Systemic hypotension should be treated initially with intravenous fluids. If fluids do not correct the hypotension, inotropic agents may be necessary. Intravenous sodium bicarbonate is recommended (level IV evidence) to treat quinine-induced sodium channel blockade (e.g., QRS prolongation). The recommended initial dosing is 1–2 mL/kg of 8.4% sodium bicarbonate repeated if necessary, aiming at obtaining a QRS width <100 msec and keeping the arterial pH < 7.55 if possible. Intravenous sodium bicarbonate is considered the treatment of choice for arrhythmias and should be used in patients with widened QRS and QT_c intervals (1–2 mL/kg of 8.4% sodium bicarbonate repeated if necessary, aiming at obtaining QRS width <100 msec, trying to keep the arterial pH < 7.55 if possible). There are no randomized controlled trials of efficacy of sodium bicarbonate in quinine poisoning, but its use is widely recommended (level IV evidence) [27]. Its use has rationale, given the class Ia action of the drug and the efficacy of sodium bicarbonate in reversing similarly induced cardiovascular effects in poisoning by tricyclic antidepressants [28]. The treatment of choice for ventricular tachycardia and torsades de pointes is overdrive pacing [57]. The threshold for pacing may have to be increased to above 1 V because the quinine-poisoned heart is relatively insensitive to pacing stimuli [20].

All antiarrhythmic drugs are potentially arrhythmogenic and should be avoided. Class I agents specifically are contraindicated, and theoretically lidocaine in particular should not be used because it may precipitate convulsions and it potentiates the action of quinine on the heart [27]. Similarly, class III drugs (e.g., sotalol, bretylium) are unsuitable because they may result in further QT prolongation and torsades de

pointes. Transvenous pacing may be indicated for complete heart block.

If an inotropic agent is required, epinephrine, norepinephrine, or both are recommended. Epinephrine is the drug of first choice, unless vasodilation predominates, when a mixture of epinephrine and norepinephrine (vasoconstrictor action) is preferred.

Ocular

Visual effects of quinine are largely untreatable because the mechanism of toxicity still is poorly understood. In the past, many measures were advocated, such as bilateral stellate ganglion block [62], retrobulbar injections [60, 70], and vasodilators, including nitrates and nimodipine [71, 72]. As with all rare conditions with some spontaneous recovery, it has been difficult to evaluate the outcome of these procedures. In my experience, however, these procedures make no difference to outcome, and therefore I would not advocate their routine use. A report suggested efficacy for hyperbaric oxygen, but the same caveats of spontaneous recovery apply [73]. The role of multifocal electroretinography and optical coherence tomography in assessing retinal damage due to quinine remains to be fully evaluated.

Central Nervous System

Quinine-induced convulsions are often short-lived, but if they persist, they should be treated with diazepam (0.1–0.3 mg/kg) or a similar benzodiazepine [20]. Phenobarbital can be used for seizures refractory to benzodiazepines [56]. Coma should be managed conventionally.

Extracorporeal Removal Techniques

Visual recovery has been taken by some workers to indicate the benefit of treatment. This improvement frequently is spontaneous and rapid. The actual amount of quinine cleared is limited, however, and cannot account for improvement.

Hemodialysis and hemoperfusion are ineffective in quinine poisoning because there is rapid

tissue distribution, a relatively large volume of distribution, and extensive protein binding. Studies of the efficacy of hemodialysis showed that in 6 h, only 25–30 mg (77–93 μmol) of quinine were removed [74]. In other patients, only a few hundred milligrams of quinine were removed by hemoperfusion [52, 75]. In one patient, charcoal hemoperfusion was complicated in one reported case by repeated clotting of the charcoal cartridge despite heparinization, thrombocytopenia, and hypoprothrombinemia. The patient died [53]. Resin hemoperfusion is equally ineffective because it removes toxicologically insignificant amounts [76].

In one report, peritoneal dialysis was claimed to remove 640 mg (1970 μmol), but no analysis of plasma quinine concentrations was done to validate these findings [77]. Other authors recorded less than 60 mg (184 μmol) removed in 24 h [78]. In another case report, plasmapheresis was similarly ineffective, removing only 8.5 mg (26 μmol) of quinine [74]. There currently is no evidence that any of the previously advocated extracorporeal elimination techniques for quinine are effective in practice.

Urinary acidification or forced diuresis is not advised. Although it may increase renal quinine excretion slightly, it would be expected to worsen cardiotoxicity. Quinine has two pK_a values (8.0 and 4.11), causing confusion in analysis of urine pH manipulation data.

Role of Octreotide

The hyperinsulinemia and resultant hypoglycemia, which complicate quinine treatment of falciparum malaria, respond to octreotide. In Thai volunteers, octreotide (100 μg intramuscularly) suppressed quinine-induced hyperinsulinemia within 15 min [79]. The effect lasted for 6 h. Octreotide (50 μg intravenously over 15 min followed by 50 $\mu\text{g}/\text{h}$ by intravenous infusion, increasing to 200 $\mu\text{g}/\text{h}$ or decreasing to 10 $\mu\text{g}/\text{h}$ as appropriate) together with intravenous glucagon or *D*-glucose or both were effective in treating hyperinsulinemia and hypoglycemia in

five patients with falciparum malaria who were treated with quinine [79]. The clinical pharmacology of octreotide is described in detail in ► Chap. 70, “Antidiabetic Agents.”

Criteria for ICU Discharge in Quinine Poisoning

Resolution of systemic hypotension

Resolution of ventricular arrhythmias and electrocardiographic abnormalities

Resolution of significant intravascular hemolysis

Resolution of convulsions

Resolution of coma

Special Populations

In children, quinine's volume of distribution is less, and its elimination half-life is shorter than in adults, and it is significantly less protein bound in children under 2 years of age [20, 56]. The free (unbound) quinine is responsible for the toxicity, and an immature blood–brain barrier and cardiovascular system may make children under 2 years especially sensitive to quinine [56]. Most cases of quinine toxicity in toddlers occur after ingestion of more than two tablets, but a report of severe toxicity has occurred after exactly 2 tablets [56]. Hence, admission for observation is recommended for a toddler ingesting more than one tablet.

In patients with malaria, there is increased protein binding, an increased elimination half-life, and a decreased volume of distribution [20]. The pharmacokinetics of therapeutic doses is altered in patients with chronic liver disease; the time to maximum plasma concentrations was prolonged, and the terminal elimination half-life was prolonged to 23.4 h versus 9.7 h in healthy controls. No change in quinine clearance was seen, however [80]. The volume of distribution of quinine is decreased in the third trimester of pregnancy, but the clearance of therapeutic concentrations is similar, and toxicokinetics is not expected to be different from the nonpregnant state [81].

Key Points in Quinine Poisoning

1. Toxicity can occur quickly (within 1–3 h).
2. Cardiovascular toxicity is a poor prognostic sign.
3. No specific therapy works in ocular toxicity.
4. Extracorporeal elimination methods are of no value.
5. Multiple-dose activated charcoal is a well-supported treatment modality.
6. Correcting hypokalemia early worsens cardiovascular toxicity.
7. Antiarrhythmic drugs may worsen cardiovascular toxicity and should be avoided.

Isoniazid (isonicotinic acid hydrazide [INH]) was first released in 1952 as a drug to treat tuberculosis. Although tuberculosis was already on the decline in the United States and much of the Western world at the time INH was released, there has since been resurgence since the 1980s largely as a consequence of human immunodeficiency virus. According to the US Centers for Disease Control and Prevention (CDC), there were 9,582 new cases of tuberculosis in the US in 2013, disproportionately affecting racial/ethnic minorities; compared to non-Hispanic whites, the TB rate was approximately six times higher in Asians and double in both non-Hispanic blacks and Hispanics [1]. Other social and medical ills, such as homelessness, overcrowding, alcoholism, and intravenous drug use, have contributed to the rise of tuberculosis infection. The CDC estimates that approximately one-third of the population has been infected by this disease, which caused 1.5 million deaths in 2013 [2].

The World Health Organization also stated that directly observed administration of antituberculin drugs in the developing world would help curb the spread. Without further public health measures such as these, it estimated that a 41% increase in new cases would be seen from 1998 to 2020, representing a change from 7.4 to 10.6 million cases [3]. The need for efficacious and cost-effective treatment has been answered largely by INH, which is useful both in combination therapy for acute TB as well as for prophylactic treatment in individuals with positive exposure testing [4]. However, with

increased use of INH came, predictably, a notably increased number of acute toxicity cases from overdose [5].

Isoniazid comes in pill, elixir, or a parenteral form. The commonly used adult dose is 5 mg/kg (maximum of 300 mg daily); the recommended pediatric dose is 10–15 mg/kg daily (also with a maximum of 300 mg). Various combination products are available, such as a capsule containing 150 mg of INH with 300 mg of rifampin (Rifamate (U.S. trade names are given as examples. Trade names may be different in other countries.)) and a tablet preparation of 50 mg of INH, 300 mg of pyrazinamide, and 120 mg of rifampin (Rifater) [6]. According to the American Association of Poison Control Centers, in 2013, there were 149 reported exposures to INH, with 55 (37%) of them being unintentional. Although 68 (46%) of these required hospital care, only 15 (10%) had major effects, and fortunately there were no deaths [7]. These data depend on voluntary reporting of exposures, however, and they undoubtedly underestimate the true incidence of INH poisonings.

Biochemistry of Isoniazid and Hydrazines

INH is also referred to as *isonicotinylhydrazide*. As its name implies, it belongs to a family of related chemicals called *hydrazines* (Fig. 1), all of which exert similar effects in acute poisoning. Hydrazine itself has many nonmedical uses. Highly combustible, it is notably used as a jet fuel; furthermore, its powerful reducing properties give it many roles in industry, where it is used in the manufacture of anticorrosive materials, dyes, textiles treatments, and various agricultural chemicals and pharmaceuticals such as pesticides.

Another notorious member of the hydrazine group is gyromitrin (*N*-methyl-*N*-formyl hydrazone) (see Fig. 1), a toxin found in *Gyromitra* mushrooms that is ultimately hydrolyzed to monomethylhydrazine in vivo. Species of this mushroom group include *G. esculenta*, *G. californica*, *G. brunnea*, and *G. infula*, and

Fig. 1 Chemical structures of isoniazid and related hydrazines

their toxicity is discussed in detail in ► [Chap. 109, “*Gyromitra* Mushrooms.”](#)

Isoniazid is produced initially as a white crystal; its injectable form is a clear to slightly greenish-yellow liquid with a pH of 6–7 and a pK_a of 1.9 [7, 8].

Pharmacokinetics of Isoniazid and Related Hydrazines

Volume of distribution: 0.6–0.75 L/kg

Cerebrospinal fluid concentrations: 90–100% of plasma 3–4 h after standard oral dose

Protein binding: 4–30%

Oral bioavailability: 90%

Metabolites: acetylisoniazid, isonicotinic acid, monoacetylhydrazine, diacetylhydrazine, isonicotinyl glycine, isonicotinyl hydrazones, methylisoniazid

Elimination: inactivated by liver acetylation* and dehydrazination, P-450 system hydrolysis, methylation; 75–96% of standard

(continued)

dose excreted in urine within 24 h as parent drug or metabolites (assuming normal renal function)

Methods to enhance elimination: hemodialysis or peritoneal dialysis in specific populations

*Acetylation rate is genetically influenced; see text.

Pathophysiology of Therapeutic and Toxic Effects

In mycobacteria, INH undergoes a series of enzymatic reactions that has the net result of inhibition of mycolic acid synthesis during cell division, producing breaks in the mycobacterial cell wall. This is its main therapeutic action as an antituberculosis drug; however, in humans, its toxicity centers upon two main effects: (1) its interference with pyridoxine (vitamin B₆) metabolism, and (2) its conversion into hydrazine metabolites.

Pyridoxine is an essential cofactor in the production of γ -aminobutyric acid (GABA), the main inhibitory central nervous system neurotransmitter. Normally, pyridoxine is converted to pyridoxine 5' phosphate (P5P) by pyridoxine kinase. P5P is a necessary coenzyme for glutamic acid decarboxylase (GAD), which is responsible for the conversion of glutamic acid to GABA (Fig. 2), the body's main inhibitory neurotransmitter. Isoniazid, however, inhibits pyridoxine kinase, resulting in a deficiency of P5P. The end result is a deficiency of GABA relative to excitatory glutamate, and a resultant excitatory state with the potential for seizures.

Secondly, INH is metabolized into hydrazine, which also binds pyridoxine, further contributing to the same excitatory state through the same mechanism described above. The acute deficiency of pyridoxal phosphate is also believed to inhibit catecholamine synthesis, contributing to cardiovascular instability and coma [9]. Furthermore, these hydrazine metabolites play a central role in INH's well-known hepatotoxicity in chronic therapeutic use [10].

Acute ingestions of 1,500 mg or less of INH can cause minor toxicity in adults and major toxicity in children. Ingestion of 6–10 g in an adult can produce severe metabolic acidosis, seizures, cardiovascular collapse, and death [11].

Clinical Presentation in Acute Toxicity

The effects of INH in acute overdose predominantly involve the central nervous system (CNS), and in milder overdoses may include psychosis, ataxia, memory impairment, nystagmus, hyperreflexia, areflexia, light-headedness, and cerebellar syndrome [12–16]. In severe acute INH poisoning, however, the classic triad consists of refractory seizures, coma, and metabolic acidosis [9, 17, 18]. The metabolic acidosis caused by INH is thought to be secondary to lactate production from seizure activity [19] and is typically associated with a high anion gap. Respiratory depression in the setting of intractable seizures, as well as reduced metabolic clearance of lactate, may also contribute. Typically, however, lactic acidemia from seizures will clear quickly once the convulsions are controlled [20].

Secondary mechanisms for the degree of acidosis have been proposed. Being structurally similar to nicotinic acid (vitamin B₃) (see Fig. 1), INH is believed to block nicotinamide-adenine dinucleotide activity, which is important for the conversion of lactate to pyruvate; however, studies did not successfully prove that this is a significant contributor to the acidosis. Ketonemia with ketonuria, as an alternate explanation for the acidosis, has been found in some cases [21]. Hyperglycemia and glycosuria have also been reported [15, 17] but is not common and overall seems to be an incidental finding. Finally, it is important to note that the intravenous (IV) preparation of pyridoxine has a pH < 3; in a RCT of 5 patients, a significant but transient elevation in the base deficit was observed [22]. Regardless of the mechanism of acidosis, it can be of impressive magnitude: in one report, a 14-year-old had a serum pH of 6.69; [23] in another, an adult patient had a pH of 6.49 [9]. Both of these patients recovered without sequelae.

Fig. 2 Inhibitory effect of isoniazid on pyridoxine-related metabolic processes. *CNS* central nervous system, *GABA* γ -aminobutyric acid

Although INH's hepatotoxic effect is of far greater consequence during chronic therapy, as detailed below, it should be noted that in one series of eight acute overdoses, six had aspartate aminotransferase levels ranging from 40 to 1,581 U/L [15]. This suggests acute hepatotoxicity as a potential complication, although fulminant hepatic failure in this setting would not be expected.

Chronic Toxicity

Peripheral neuropathy is a side effect of long-term INH therapy that is believed to result from pyridoxine deficiency. In a 1954 case report, therapy with pyridoxine relieved the peripheral neuropathy of a patient taking INH. The neuropathy recurred after pyridoxine therapy was discontinued [24]. On a microscopic level, evaluation of patients with INH-associated peripheral neuropathy has shown wallerian degeneration [25]. Risk factors for INH-induced peripheral neuropathy include malnutrition, pregnancy, diabetes, alcoholism, and slow acetylator status. Because pyridoxal phosphate is removed by hemodialysis, patients receiving HD chronically are theoretically at risk for neurotoxicity [26]. In a study of 38 children receiving INH, 13% were found to be pyridoxine deficient, although none had definitive symptoms of the deficiency

[27]. Doses of INH greater than 6 mg/kg/day also are considered to place the patient at risk for peripheral neuropathy. Pellagra also may result from deficiency of pyridoxal phosphate. Optic neuritis is another recognized adverse effect of INH therapy [28, 29] and may be exacerbated by concomitant use of ethambutol, another antituberculous drug with established optic toxicity.

Although rhabdomyolysis has been reported in patients taking INH intermittently, it is primarily a consequence of seizure activity [30]. Other, less commonly reported adverse effects of INH include isolated fevers, rash, worsening of asthma symptoms, pancreatitis, red blood cell aplasia, and a lupus-like syndrome [31–39].

Hepatotoxicity in Chronic Use

One of the interesting properties of all hydrazines is the ability to cause hepatotoxicity, although attempts to quantify this burden are hampered by the small number of studies, varying definitions of hepatotoxicity, heterogeneous patient populations, and confounding causes of liver injury, such as concomitant hepatotoxic medications. Elevations of liver function tests are typically transient and normalize despite continued therapy with the drug, a phenomenon known as “adaptation”

[40]. Nonetheless, it is estimated that 20% of patients receiving INH develop an elevation in liver function tests [41, 42]. In contrast, other studies found incidences ranging from 0.15% to 0.6%, with a trend toward higher rates of hepatotoxicity in women [43–45]. In many of these studies, serial serum transaminases were not performed, and toxicity was defined on the basis of clinical findings only.

Elevations in liver transaminases can appear within the first 2 weeks of therapy to 6 months after initiation with most cases developing within the first 3 months of therapy. Some authors have recommended discontinuing the use of INH when transaminases exceed three times the normal values. Clinically, a patient with INH hepatotoxicity may voice vague digestive complaints (55%) or viral-like complaints (35%), according to one review comprising 114 patients [46]. A 1972 report described 2,321 patients who required INH prophylaxis, 19 of whom (mean age 49.4 years) developed clinical symptoms of hepatic injury, occurring within the first 2 months in 9 patients [47]. This attracted the attention of the US Public Health Service, which in 1972 undertook a surveillance study of 13,838 persons taking INH prophylaxis therapy and identified 8 deaths (0.06%). In the 21 cities examined, the rate of hepatotoxicity varied; 92 cases were determined to be probably related to INH, 82 cases were possibly related, and 22 cases had insufficient data [48]. These data also showed the higher incidence of hepatotoxicity in persons older than age 35 years and persons with daily alcohol intake. In 1983, the American Thoracic Society changed its recommendation for INH prophylaxis, recommending chemoprophylaxis for persons at increased risk of developing active tuberculosis and persons younger than 35 years. If patients are at high risk for developing tuberculosis and they are older than 35 years old, periodic liver function tests are recommended [49].

The fatality rate of patients with fulminant hepatitis has been reported to be 5% [48, 50]. There seems to be a higher mortality in women, particularly during pregnancy and in the postpartum period [51, 52]. Risk of hepatotoxicity also seems to increase with age and in patients on

combination therapy with INH and rifampin [45]; however, a hepatitis B carrier state does not seem to confer more risk [53]. Ethanol consumption is considered a significant factor by some authors; however, this is difficult to quantify in retrospective evaluations [48, 54]. Liver transplantation has provided rescue treatment in select cases of fulminant hepatitis [55, 56].

Since hepatotoxicity is thought to be at least in part due to directly toxic effects of acetylhydrazine, one of INH's metabolites, there has been considerable research focused on acetylation status, which is genetically determined and does not change with age. The slow acetylation phenotype is found in 50–60% of American whites and blacks, while the fast acetylator phenotype is found primarily in Japanese and Inuit populations. Slow acetylators exhibit longer elimination half-life and higher plasma concentrations of INH and acetylhydrazine, particularly if they are taking high INH doses (>10 mg/kg/day). Both acetylhydrazine and the nonacetylated metabolite, hydrazine, yield hepatotoxic intermediates [57, 58]. Although a preponderance of the literature has focused on these genetic determinants, more recent research has revealed a possible role for other mechanisms, such as activation of the immune system, disruption of endogenous metabolism, and mitochondrial dysfunction [59].

Food and Drug Interactions

Although reports of food and drug interactions with INH are infrequent, the potential for interactions does exist. INH weakly inhibits the enzyme monoamine oxidase (MAO) and is a congener of isocarboxazid, an early MAO inhibitor used as an antidepressant and antituberculosis agent. The typical drug and dietary precautions given to patients on MAO inhibitors generally are not expanded, however, to include INH. It is likely that because INH is only a weak inhibitor of MAO, patients often appear to tolerate the drug without dietary precautions. As an MAO inhibitor, however, INH decreases the metabolism of tyramine, present in some wines, cheeses, and soy products. Increased sensitivity to dietary

tyramine is associated with long-term INH administration and is manifested by flushing, palpitations, pruritus, headache, nausea, vomiting, and hypertension [60].

Reports of other notable drug interactions with INH have surfaced. A case of meperidine and INH in combination resulting in hypotension has been reported [61]. Caution has been advised when combining INH and tricyclic antidepressants [62, 63]. Aside from the weak MAO inhibition attributed to INH, it inhibits the metabolism of several benzodiazepines, phenytoin, carbamazepine, warfarin, and valproic acid [64, 65]. Rifampin administration may induce the formation of hepatotoxic hydrazine metabolites. Patients who are slow acetylators are considered to be at greater risk for hepatitis when taking both of these drugs [66]. Isoniazid also inhibits the enzyme diamine oxidase, which metabolizes histamine.

Some INH drug interactions are thought to result from INH-induced inhibition of the cytochrome isoenzyme CYP2E1 [67], the same enzyme responsible for metabolism of two of the world's most commonly consumed substances: acetaminophen and ethanol. Acetaminophen clearance has been shown to decrease by 15.2% when INH is given [68]. Paradoxically, INH not only inhibits but also induces CYP2E1. This is the basis of what seems to be an increased risk of hepatotoxicity in patients who take acetaminophen during INH therapy [69, 70].

Industrial Hydrazines

Industrial hydrazines have toxic effects similar to those of INH, including seizures and hepatotoxicity. Additionally, they can produce direct tissue damage. Hydrazines are corrosive to the skin, resulting in manifestations ranging from simple itching to severe burns. Solutions with hydrazine concentrations greater than 25% are likely to produce significant dermal injury. High ambient concentrations can lead to hydrazine vapor exposure with irritation of mucous membranes and eyes. Similarly, concentrated vapor exposure can result in irritation of the respiratory tract,

producing cough, shortness of breath, or pulmonary edema [71]. Combustion of hydrazines liberates nitrogen oxides, which can be toxic to the lung parenchyma. Methemoglobinemia (see ► Chap. 30, “Toxicant-Induced Hematologic Syndromes”) and hemolysis may occur after hydrazine exposures.

Diagnosis of Hydrazine Poisoning

Toxic exposures associated with seizures, metabolic acidosis, or both include cyanide, salicylates, tricyclic antidepressants, theophylline, iron, ibuprofen, cocaine, amphetamines, phencyclidine, ethylene glycol, and methanol. Ethanol/benzodiazepine withdrawal also should be considered in the differential diagnosis. Hyperglycemia and acetonuria should suggest the diagnosis of diabetic ketoacidosis, particularly if the history does not include seizure activity. Isoniazid overdose always should be considered in a patient with new onset of seizures of unknown etiology, particularly if the patient is from a tuberculosis-prone population. Generally the diagnosis is made clinically and based on the history of exposure. Laboratory testing usually cannot verify a diagnosis of INH poisoning within a clinically useful time frame. Serum transaminases at baseline and regular intervals are required to identify INH-induced hepatitis.

Treatment of Isoniazid and Hydrazines Poisoning

Skin and Eye Decontamination of Hydrazine Chemicals

Skin and eye decontamination for industrial hydrazine exposure is crucial because these agents are very corrosive. Skin decontamination focuses on administration of copious amounts of water and prompt removal of contaminated clothing, jewelry, watches, and shoes. If possible, decontamination should occur away from other contacts. The patient may be able to participate in decontamination by self-removal of clothing

and self-washing of the skin. If minimal vapor exposure has occurred in an asymptomatic patient, removal of clothing may be all that is required. If doubt exists about the extent of exposure, water decontamination is advisable. The concentration of the chemical also determines the hazard, but for most hospital and prehospital medical providers, that information may not be immediately available. Because hydrazine and monomethylhydrazine are flammable liquids, decontamination should take place away from any possible sources of ignition, e.g., electrical switches, radios, and other electronics. Eye decontamination consists of irrigation with large amounts of water, which may be facilitated by a Morgan lens after topical anesthesia. Because hydrazines are alkalis, the goal of ocular decontamination is to restore a constant pH of 7.0 to the conjunctival sac.

Medical Management

As with all overdoses, supportive care is crucial in the management of intoxication by INH or other hydrazine compounds, with close attention to vital signs, monitoring for early signs of cardiovascular collapse or airway compromise. Secure intravenous access is of particular importance because seizures may occur suddenly, although they are typically preceded by hyperreflexia or areflexia. Supplemental oxygen, fluid volume support, and maintenance of a patent airway are immediate priorities.

The clinician should consider carefully the risks of the various gastrointestinal decontamination methods versus their limited benefit, and these should not be used in a seizing patient due to the risk of aspiration. Activated charcoal, which has been shown to adsorb INH well, may be considered if appropriate [72]. There are no data, however, indicating that gastrointestinal decontamination alters outcome in these patients. The clinician should consider carefully the risks of GI decontamination methods versus limited data on efficacy. Activated charcoal should not be administered to a patient with seizures due to the risk of aspiration. Gastrointestinal

decontamination is discussed further in ► Chap. 3, “Therapeutic Approach to the Critically Poisoned Patient.”

In patients with profound metabolic acidosis, administration of intravenous sodium bicarbonate may be warranted. Sodium bicarbonate should not be used to correct metabolic acidosis in the absence of aggressive efforts to control seizure activity because most of the acidosis is caused by the neuromuscular hyperactivity that occurs with seizures. Rhabdomyolysis should be assessed by following serum creatine phosphokinase or urine myoglobin. In cases of severe rhabdomyolysis, urine alkalization to pH greater than 6.5 may be beneficial.

Indications for ICU Admission in Isoniazid and Related Hydrazines Poisoning

Prolonged or severe metabolic acidosis

Multiple seizures

Significant rhabdomyolysis

Depressed mental status

Hemodynamic instability

Seizures not easily controlled by pharmacologic interventions

Targeted Treatment

Pyridoxine is the mainstay for treating INH (or other hydrazine)-induced seizures, at a dose to match the estimated amount of INH ingested or to a maximum of 5 g (Grade II-3 evidence) [13, 17, 18, 23]. If the dose ingested is unknown, 5 g should be given. This dose may be repeated if needed [17]. The effects are usually dramatic and of quick onset; in one case series, 5 patients demonstrated cessation of seizures, correction of acidosis, and an improvement in mental status within two hours of receiving pyridoxine. Additionally, pyridoxine's effect appears to not be dependent on the time to onset of seizures or coma; it has been shown to prevent seizures if given before their onset, as well as to quickly reverse an INH-induced coma [18, 73].

The high doses of pyridoxine required for adequate therapy mean, unfortunately, that many

hospitals do not have adequate stores of it; it may have to be procured from other hospitals or pharmacies. In a survey of US hospitals with pediatric emergency medicine fellowships or emergency medicine residencies, immediate availability of the recommended 5-g dose was lacking for half of the institutions, and the dose was not kept in the emergency department in an even greater adult proportion of responding programs [74]. One pediatric case series found that the average delay to its administration was 5.8 h [6]. Areas where tuberculosis is relatively endemic should strongly consider keeping pyridoxine close at hand in the emergency department. Poison centers may also be a reference for obtaining information on antidote stockpiles.

Large doses of pyridoxine are not benign, although the toxic dose is not known [75]. A well-known case has been reported where 52 g of pyridoxine produced no adverse effects [17], which was echoed in a case series where 357 mg/kg produced no adverse effects [76]. Massive amounts of pyridoxine were tolerated well in human pharmacologic studies [77]. Severe peripheral neuropathies, some permanent, have been reported in very high short-term and high long-term pyridoxine dosing (0.5–2 g/day) [78, 79]. The clinical pharmacology of pyridoxine is discussed in ► Chap. 163, “Pyridoxine.”

Due to the INH's effect on GABA, it follows that drugs that increase GABA concentration, such as benzodiazepines and barbiturates, could also be of therapeutic benefit [80]. Although case reports suggest that monotherapy with these agents without pyridoxine can rarely provide full control of INH-induced seizures, they have been demonstrated to have a valuable additive effect when given in conjunction with pyridoxine. They also have the significant advantage of being readily available in most acute care settings.

Benzodiazepines have been well demonstrated to potentiate the effects of pyridoxine for INH-induced seizures; among these, diazepam is the most cited in case reports. Phenobarbital is also a rational choice for adjunctive therapy, although its induction of INH's metabolism into

toxic hydrazines has been cited as a potential disadvantage [81]. Thiopental, a short-acting barbiturate, has been used with success in a severe case of toxicity unresponsive to 40 mg IV diazepam and 1 g IV phenobarbital (Grade III evidence) [82].

Phenytoin, which exerts its anticonvulsant actions through affecting sodium channels rather than GABA receptors, is theoretically and empirically ineffective in the treatment of INH-induced seizures. Furthermore, INH is a potent inhibitor of phenytoin metabolism, hindering phenytoin's elimination. In both theory and practice, this has led to phenytoin toxicity [83], the signs of which (lethargy, nystagmus, and ataxia) would be difficult to perceive in a comatose patient [84].

Other Hydrazines

Reports of severe hydrazine and monomethylhydrazine poisoning in the medical literature are few compared with reports involving INH. However, the use of pyridoxine is recommended on theoretical grounds for seizures and coma in victims of serious industrial exposure to hydrazine or major exposures to gyromitrin-containing mushrooms. Because gram-for-gram dosing of pyridoxine may not be calculable in an occupationally exposed patient, the generally accepted empirical adult dosing for seizure control is 5 g administered intravenously as a bolus.

Hemodialysis

Hemodialysis is theoretically likely to enhance INH clearance based on its low degree of protein binding and relatively small volume of distribution. Hemodialysis is generally unnecessary, however, if aggressive supportive care, pyridoxine, and sodium bicarbonate are provided, especially given INH's short elimination half-life and the typically short duration of severe symptoms after INH overdose. Patients non-responsive to

the above outlined treatment, or without the ability to clear INH and its metabolites because of renal failure, could benefit from peritoneal dialysis or hemodialysis (Grade III evidence) [14, 85].

Criteria for ICU Discharge in Isoniazid and Related Hydrazines Poisoning

Resolution of metabolic acidosis and all seizure activity

Return to baseline mental status

Resolving rhabdomyolysis, if present

Common Errors in Isoniazid and Related Hydrazines Poisoning

Overaggressive pyridoxine therapy for prolonged periods

Failure to recognize coma as a toxic effect of overdose from isoniazid

Failure to recognize potential hazards of industrial hydrazines from a contaminated patient

Forgetting the usefulness of adjunctive benzodiazepine therapy in the treatment of seizures

Key Points in Isoniazid and Related Hydrazines Poisoning

1. Never use ipecac syrup.
2. Seizures are most likely to present within the first 3 h of ingestion.
3. Pyridoxine is the drug of choice for seizures.
4. Benzodiazepines may be useful as adjunctive therapy until sufficient pyridoxine is available.
5. Monitor renal function and hydration status if the patient develops multiple or prolonged seizures.
6. Use sodium bicarbonate therapy for metabolic acidosis that persists despite cessation of seizures.

Rifampin

Rifampin is a macrocyclic antimicrobial agent synthetically derived from many generations of rifamycin B, a virtually inactive metabolite of *Streptomyces mediterranei*. In 1968, an active product was conceived, rifamycin SV, which showed activity against gram-positive organisms [1]. Rifampin, a hydrazone derivative of 3-formylrifamycin SV, is used today in various settings as a broad-spectrum agent against gram-positive organisms (*Staphylococcus aureus*, *Staphylococcus epidermidis*, *Neisseria meningitidis*, *Haemophilus influenzae*) and gram-negative organisms (*Escherichia coli*, *Klebsiella*, *Proteus*, *Pseudomonas*) [2]. More commonly, rifampin is used as a synergistic, bactericidal agent against tuberculous and non-tuberculous mycobacteria.

Clinical Pharmacology

The structure of rifampin is shown in Fig. 1.

Pharmacokinetics of Rifampin

Volume of distribution: 0.97–1.6 L/kg

Protein binding: 75–90 %

Mechanism of clearance:* 7 % renal

Active metabolites: 25-desacetylrifampin, 3-formylrifamycin

Methods to enhance clearance: multiple-dose activated charcoal

*Assumes normal renal function.

Pathophysiology

Rifampin binds to DNA-dependent RNA polymerase in bacteria and prevents initiation of messenger RNA synthesis in nonmammalian cells (Fig. 2) [3]. Rifampin induces CYP3A4, resulting in the increased metabolism of numerous drugs (Table 1). Of particular concern in the critical care setting is the increased metabolism (and decreased action) of anticoagulants and corticosteroids.

Clinical Presentation

Daily use of rifampin has few serious side effects. Red-orange discoloration of body fluids (e.g., urine, tears) is common with both therapeutic and toxic dosing, with increased incidence in a dose-dependent fashion [4]. Mild elevation of hepatic transaminases and cholestatic jaundice occur, especially when rifampin is used in combination with isoniazid, but symptomatic hepatitis or liver failure tends to be limited to elderly or undernourished patients and to patients with chronic liver disease [5, 6]. When rifampin is administered on an intermittent basis (once-weekly or twice-weekly dosing), or reintroduced after prolonged discontinuation, some patients experience a flu-like syndrome, including fever and chills, headache, malaise, and weakness with colitis and eosinophilia [7, 8]. Hemolytic anemia and thrombocytopenia also occur in these circumstances and may be antibody mediated. Acute renal failure has been reported, including rapidly

Fig. 1 Chemical structure of rifampin

Fig. 2 Mechanism of rifampin action. The drug binds to the β -subunit of DNA-dependent RNA polymerase and inhibits initiation of (but not ongoing) RNA synthesis. (a) Drug is absent. (b) Drug is bound to the polymerase and distorts the conformation of the enzyme so that it cannot initiate a new chain (From Brody H, Larner J, Minneman KP, et al: *Human Pharmacology: Molecular to Clinical*, 3rd ed. St. Louis, Mosby, 1998, p 725, with permission.)

HMG-CoA 3-hydroxy-3-methylglutaryl-coenzyme A

progressive glomerulonephritis, acute interstitial nephritis, and light-chain proteinuria [9]. The mechanism for renal failure may occur secondary to hemoglobinuria in association with intravascular hemolysis or mediated by rifampin-dependent IgG and IgM antibodies cross-reacting with the I antigen on tubular epithelium [10]. Rifampin-

induced lupus-like syndrome also has been reported when rifampin is used in combination with clarithromycin or ciprofloxacin and may involve autoantibody production [11]. Drowsiness and confusion have been observed in massive overdoses. Anaphylactoid reactions can occur with both therapeutic use and overdosage and may require management in a critical care setting.

Diagnosis

Rifampin serum concentrations are available; correlation with frequency or severity of toxicity is lacking. Determination of hepatic transaminases and fractionated bilirubin may be beneficial, especially when used in combination with isoniazid or other potential hepatotoxins or when used in the elderly. These laboratory parameters should be followed closely in symptomatic patients. There are no commercially available tests for the detection of rifampin-dependent antibodies [12].

Treatment

Discontinuation of rifampin usually is sufficient to correct mild elevations in hepatic transaminases, rifampin-induced renal failure, and

rifampin-induced flu-like syndrome [5, 10]. There are no formally validated or accepted general criteria for discontinuation, however. Red-orange skin discoloration is treated with simple cleansing [4]. In cases of acute liver failure, liver transplantation may be necessary [13, 14]. Supportive care is adequate in most patients with rifampin toxicity. There are no specific antidotes. Several other specific therapeutic interventions are described subsequently.

Indications for ICU Admission in Rifampin**Poisoning**

Severe anaphylactoid reaction

Fulminant hepatic failure

Acute renal failure requiring dialysis

Activated Charcoal

Single-dose activated charcoal may decrease absorption if large amounts of rifampin have been ingested and the charcoal can be administered in the first hour. However, there are no data indicating whether activated charcoal alters the outcome or clinical course after rifampin ingestion. Multiple-dose activated charcoal may increase rifampin clearance; however, improvement in clinical outcome has not been demonstrated and cannot be justified based on the existing data [15].

Extracorporeal Removal

Rifampin's high protein binding and large volume of distribution preclude elimination by extracorporeal removal.

Special Populations**Pediatric Patients**

There are no special considerations regarding rifampin in pediatric patients.

Pregnant Patients

Rifampin has been shown to cause fetal malformations in mice; clinical correlation in humans has not been reported. Rifampin is recommended therapy in pregnant females with active tuberculosis infection.

Elderly Patients

There is an increased incidence of hepatic and renal injury associated with rifampin in elderly patients [6, 9].

Chronic Liver Disease Patients

Patients with chronic liver disease are at increased risk for rifampin-induced hepatic failure [14].

Dapsone

Dapsone is a synthetic sulfone antimicrobial used for the prophylaxis of *Pneumocystis carinii* in immunocompromised patients with documented adverse reactions to trimethoprim-sulfamethoxazole [16]. Sulfones have experimental activity against many mycobacteria, as they are used clinically as a bacteriostatic agent in the treatment of *Mycobacterium leprae*, although drug resistance is increasing [17]. Occasionally, dapsone is used to treat chloroquine-resistant malaria, although resistance to dapsone therapy is increasing as well [18]. Dapsone is capable of suppressing neutrophil migration by blocking integrin-mediated adherence [19]. For this reason, it has been successful in the treatment of dermatologic disorders, such as dermatitis herpetiformis, pemphigus vulgaris, pyoderma gangrenosum, psoriasis, and systemic lupus erythematosus [20]. The often-touted use of dapsone as a treatment for the necrotic lesions caused by the brown recluse spider is poorly supported [21].

Fig. 3 Chemical structure of dapsone

Clinical Pharmacology

The structure of dapsone is shown in Fig. 3.

Pharmacokinetics

Volume of distribution: 1.0–1.5 L/kg

Protein binding: 70–90 %

Mechanism of clearance:* 15 % renal

Active metabolite: monoacetyldapsone

Methods to enhance clearance: multiple-dose
activated charcoal, charcoal hemoperfusion

*Assumes normal renal function.

Pathophysiology

Dapsone is a bacteriostatic antimicrobial agent that binds to dihydropteroate synthase, which catalyzes the conversion of para-aminobenzoic acid and pteridine into dihydropteroic acid in the first step of folic acid synthesis. Folic acid is essential for the formation of methionine, which is necessary for nucleic acid synthesis. Thus, bacteria that depend on intrinsic folic acid production are adversely affected by dapsone [18].

Dapsone causes oxidant stress to the hematologic system. Hemolysis and methemoglobinemia may occur either separately or together. Dapsone-derived free radicals, formed by the biotransformation of dapsone into free arylamines and hydroxylamines, bind to the red blood cell membrane and to hemoglobin, leading to the formation of precipitated, denatured proteins (Heinz bodies). Heinz bodies attach to red blood cell membranes, inducing affected erythrocytes to be destroyed by

the reticuloendothelial system [22]. Dapsone and other oxidants interact with the iron cation within hemoglobin as electron acceptors, thus oxidizing divalent iron (Fe^{2+}) to trivalent iron (Fe^{3+}) and inducing the formation of methemoglobin, which is unable to transport oxygen. Induction of methemoglobinemia shifts the oxygen-hemoglobin dissociation curve to the left, thus further impairing oxygen delivery to tissues. Although red blood cells carry a natural defense (reduced glutathione) against oxidizing agents, these stores can be depleted rapidly in cases of drug-induced hemolysis or methemoglobinemia, which may occur separately or together [23]. Oxidant stressors on erythrocytes are discussed in greater detail in ► Chap. 30, “Toxicant-Induced Hematologic Syndromes.”

Sulfhemoglobinemia also may be induced by dapsone. Sulfhemoglobin is incapable of carrying oxygen; however, the oxygen-hemoglobin dissociation curve is shifted to the right, which enhances overall oxygen delivery to tissues by remaining oxyhemoglobin [24].

Dapsone-induced maculopathy is presumed to occur secondary to the physical effects of red blood cell fragmentation in the vascular supply to the macular and perimacular regions of the eye, resulting in ischemic necrosis [25]. Dapsone-induced acute renal failure is thought to occur via a similar microvascular compromise [26]. The “sulfone syndrome” (described below) may be induced by antibodies directed toward the free arylamine and hydroxylamine metabolites of dapsone [26].

Clinical Presentation

Hemolysis and methemoglobinemia are the most well-described toxicities of dapsone. Although doses of greater than 200 mg/day are thought to be required to induce hemolysis in adults, the induction of methemoglobinemia seems to be a critical adverse effect of standard therapy. Hemolytic anemia may manifest with tachycardia, pallor, jaundice, hypoxia, acidemia, and shock.

Methemoglobinemia presents with cyanosis after blood methemoglobin concentration exceeds 1.5 g/dL. Excessive hemolysis and/or marked decrease in hemoglobin concentration may cause cyanosis to disappear.

The clinical presentation of dapsone-induced methemoglobinemia may occur immediately after exposure or may be delayed up to 3 days. Clinical effects may be prolonged and recurrent, owing to the drug's delayed peak (up to 20 h in overdose) and long half-life (30 h in therapeutic settings, up to 77 h in overdose) [27, 28]. Children younger than 4 years may express significantly higher methemoglobin concentration secondary to a relative deficiency in reduced nicotinic adenine dinucleotide (NADH)-dependent methemoglobin reductase [29], the enzyme responsible for reducing methemoglobin to hemoglobin.

The clinical presentation of sulfhemoglobinemia is generally similar to, but less severe than, that of methemoglobinemia. Both processes present with a falsely low pulse oximetry readings and normal arterial blood gas PO_2 . Patients with sulfhemoglobinemia rarely present with significant cyanosis, because the amount of sulfhemoglobin generated in most cases is less than 5 % of total hemoglobin [24].

Other nonspecific effects include nausea, vomiting, rashes, and psychosis. Controversial evidence suggests that dapsone may cause axonal degeneration, resulting in peripheral neuropathy [27]. Although dapsone is used as a treatment for leprosy, exacerbation of the condition has also been reported with therapy [17]. Agranulocytosis is a rare effect of dapsone therapy [30]. Also reported is the "sulfone (hypersensitivity) syndrome," which may develop approximately 2 months after starting long-term treatment with dapsone; methemoglobin and hemolytic anemia occur, accompanied by fever, exfoliative dermatitis, and fulminant hepatic necrosis with jaundice [31].

Diagnosis

Dapsone poisoning should be considered in any immunocompromised patient presenting with cyanosis or signs of hemodynamic instability.

Serum concentrations of dapsone are available but do not correlate with signs of toxicity [23]. Long half-life of dapsone and the gradual cumulative process of injury to red blood cells may delay signs of toxicity; patients may be asymptomatic for several hours before developing methemoglobinemia or hemolysis in overdose. In dapsone-induced hemolysis, hemoglobin concentrations may be low or normal, but the appearance of Heinz bodies on the peripheral blood smear may be an early indication of hemolysis. Reticulocyte count also may be elevated, but is typically delayed for several days [22]. During hemolysis, testing for glucose-6-phosphate dehydrogenase (G6PD) activity may not be clinically useful, because these patients have a predominance of young peripheral red blood cells with possibly normal G6PD activity [23]. In dapsone-induced methemoglobinemia, cooximetry can be used to measure methemoglobin concentrations but may read sulfhemoglobin falsely as methemoglobin. Most cooximeters are not designed to distinguish between methemoglobin and sulfhemoglobin [24]. Pulse oximetry is potentially misleading and should not be used alone as a diagnostic tool to assess the degree of tissue hypoxia; however, a low pulse oximetry reading that does not change with oxygen therapy should raise the suspicion of methemoglobinemia [32].

Treatment

Discontinuation of dapsone with subsequent observation usually is sufficient for most cases of mild dapsone-induced hemolytic anemia and methemoglobinemia. Normal bone marrow production typically compensates for mild red blood cell loss. Exchange or conventional (packed red blood cell) transfusion may be required in severe cases. Reduction of methemoglobin in red blood cells normally occurs predominantly via the action of NADH cytochrome- b_5 reductase. This mechanism decreases methemoglobin content by approximately 15 % per hour [33]. Slower endogenous detoxification rates may reflect intrinsic defects in cytochrome- b_5 reductase activity or ongoing production of

methemoglobinemia. Pulse oximetry typically shows falsely low measurements in the settings of sulfhemoglobinemia and methemoglobinemia [27]. Management of oxidant-induced hemolysis and methemoglobinemia is discussed in detail in ► Chap. 100, “Irritant and Toxic Pulmonary Injuries.”

Gastrointestinal Decontamination

Single-dose activated charcoal may decrease dapsone absorption if given within an hour of ingestion. However, there are no data indicating whether activated charcoal administration alters the outcome or clinical course after dapsone overdose.

Indications for ICU Admission in Dapsone Poisoning

Severe hemolysis or methemoglobinemia with secondary hypoxia, cardiovascular impairment, or shock
Renal failure requiring dialysis
Hepatic failure and/or presence of severe cutaneous involvement in the “sulfone syndrome”

Extracorporeal Removal

Hemodialysis is not likely to be of benefit because of dapsone’s high protein binding and large volume of distribution (see Table 1). Charcoal hemoperfusion may decrease the long half-life of dapsone in severe cases that do not respond to conventional treatment [34] (Grade III recommendation). There are no studies documenting improvement, however, in clinical outcome or hospital course with hemoperfusion.

Methylene Blue

Methylene blue’s antidotal action reflects its role as a cofactor for reduced nicotinic adenine dinucleotide phosphate (NADPH) methemoglobin

reductase. This enzyme, normally a minor contributor to methemoglobin reduction, uses products from the hexose monophosphate shunt as a source of electrons for the reduction of methemoglobin. The conversion of glucose-6-phosphate to phosphogluconate by G6PD in the first step of the pentose monophosphate shunt provides electrons for the conversion of NADP to NADPH. Methylene blue first is reduced to leukomethylene blue by electron donation from cellular NADPH stores. Leukomethylene blue, through the actions of NADPH methemoglobin reductase, donates these electrons to methemoglobin, reducing the Fe^{3+} in the heme group to the Fe^{2+} state and consequently reverting back to methylene blue (see ► Chap. 30, “Toxicant-Induced Hematologic Syndromes”). The typical dose of methylene blue is 1–2 mg/kg intravenously over 5–10 min [35]. This can be repeated, if necessary, although the author recommends waiting approximately 1 h unless the patient is unstable (Grade III recommendation). If cyanosis persists, one must consider ongoing methemoglobin production, G6PD deficiency, or sulfhemoglobinemia. There is no antidote for sulfhemoglobinemia.

Other Treatments

Multiple-dose activated charcoal may increase dapsone clearance, but improvement in clinical outcome has not been shown, and the data does not support its routine use. However, there is a role for multidose activated charcoal in patients with protected airways and who ingested a life-threatening amount of dapsone [15] (Grade III recommendation). Details on the administration of multidose activated charcoal are given in ► Chap. 3, “Therapeutic Approach to the Critically Poisoned Patient.” Severe methemoglobinemia and sulfhemoglobinemia unresponsive to conventional therapy may be treated with exchange transfusion [32] (Grade III recommendation). Sulfone syndrome responds to the cessation of dapsone use. The administration of systemic corticosteroids is advocated in case studies, although controlled trials documenting efficacy are lacking [27, 31].

Special Populations

Pediatric Patients

Dapsone doses of 100 mg (one tablet) in a child have been reported to cause hemolysis and methemoglobinemia [32].

Pregnant Patients

Studies documenting teratogenicity in humans are lacking. Dapsone is a possible cause of neural tube defects via impairment of the folate synthesis pathway. The author recommends that nursing mothers avoid dapsone due to the potential for hemolysis and methemoglobinemia in the infant.

Elderly Patients

There are no special considerations in elderly patients.

Patients with Glucose-6-Phosphate Dehydrogenase Deficiency

Patients with G6PD deficiency have a decreased red blood cell capacity to produce adequate levels of NADPH. NADPH is required to maintain appropriate stores of reduced glutathione, the red blood cell's primary defense against oxidants. G6PD-deficient patients are more susceptible to developing hemolysis and methemoglobinemia after dapsone administration. There may be an increased risk of hemolysis or methemoglobinemia induced by methylene blue administration because the antidote itself is a mild oxidant that competes for the same NADPH required for maintenance of glutathione stores [36]. If methylene blue is administered to a known or potentially G6PD-deficient patient, they should be monitored closely for hemolysis and worsening of methemoglobinemia. If any of these occur, methylene blue should be discontinued. Patients of African, South Asian, or Middle Eastern descent have a higher prevalence of G6PD deficiency. In a patient in

whom methylene blue is contraindicated on the basis of G6PD deficiency, exchange transfusion may be beneficial [32].

Vancomycin

Vancomycin is a complex glycopeptide antimicrobial agent derived from *Streptomyces orientalis* bacteria found in the soil in the Far East, used primarily as a parenteral agent against gram-positive bacterial infections, particularly resistant strains of *S. epidermidis* and *S. aureus*, and as a synergistic agent with aminoglycosides against resistant *Enterococcus*, viridans streptococci, *Streptococcus pyogenes*, and *Streptococcus pneumoniae* [37]. Vancomycin is used orally in patients with pseudomembranous colitis secondary to *Clostridium difficile* [38] and in bone marrow transplant patients to maintain gastrointestinal sterility during transplantation [39].

Pharmacology and Pharmacokinetics

The structure of vancomycin is shown in Fig. 4.

Pharmacokinetics of Vancomycin

Volume of distribution: 0.11–0.39 L/kg

Protein binding: 30–55 %

Mechanism of clearance:* 79 % renal

Active metabolites: none

Methods to enhance clearance: hemodialysis, hemodiafiltration

*Assumes normal renal function

Pathophysiology of Therapeutic and Toxic Effects

Vancomycin inhibits cell wall synthesis in bacteria by binding to the D-alanyl-D-alanine moiety of cell wall precursors. Transpeptidase is unable to catalyze the linkage of D-alanine to glycine into the peptidoglycan chain, and cell wall synthesis

children, with a first-phase half-life ($t_{1/2\alpha}$) of 0.80 h and a second-phase half-life ($t_{1/2\beta}$) of 5.63 h. Serum vancomycin concentrations measured earlier than 4 h after a dose may not reflect post-distribution peak concentrations. Measured peak serum concentrations of vancomycin in children may not be predictive of toxicity [50, 51].

Treatment

Reducing the infusion rate and dilution prior to intravenous infusion may prevent the occurrence of red man syndrome. Concomitant or prior administration of diphenhydramine also has been effective [52]. Ototoxicity and nephrotoxicity are generally reversible with dose readjustment or discontinuation [53].

Gastrointestinal Decontamination

Vancomycin is poorly absorbed orally, so gastrointestinal decontamination is not necessary.

Indications for ICU Admission in Vancomycin Poisoning
Severe anaphylactoid reaction

Extracorporeal Removal

Hemodialysis can remove vancomycin effectively in patients with impaired renal function [50, 53]. Charcoal hemoperfusion has been implemented, but superiority over hemodialysis is not documented.

Special Populations

Pediatric Patients

Dosing intervals may need to be adjusted in neonates, secondary to relatively decreased clearance of vancomycin by neonatal kidneys. High vancomycin trough levels in neonates may necessitate twice-daily or once-daily dosing [50].

Pregnant Patients

Because vancomycin appears in cord blood, it is presumed to raise the risk of fetal ototoxicity and nephrotoxicity, but clinical correlation has not been documented.

Elderly Patients

Dosing intervals may need to be adjusted for hepatic or renal insufficiency.

Iron poisoning is a well-respected historically significant toxicologic problem. In the pediatric population, iron has been regarded as the most fatal of all toxic exposures [1]. Fortunately because of regulations on packaging in the USA and other countries, serious poisonings have declined [2]. Visible warning labels and dispensing of tablets and capsules in blister packages have limited the dose a child might consume. For example, iron poisoning fatalities in children less than 6 years of age in the USA decreased from 29 in 10 years before the packaging regulation to one death in the 5 years after [3]. Total reported exposures in children younger than 6 years old have declined from 3026 in 1995 to 2139 in 2013 in the USA [4, 5]. The other patient population at risk is suicidal patients, most notably women of childbearing age with access to iron products. In 2013, 28% of iron exposures in the USA occurred in patients who were teenagers or older [5]. Despite the significant toxic potential of iron, death and serious sequelae are uncommon because most exposures are unintentional and involve negligible amounts.

Biochemistry and Pharmacokinetics of Iron

The primary functions of iron include participation in oxygen delivery as a constituent of hemoglobin and myoglobin and production of adenosine triphosphate via oxidative phosphorylation. It is a highly reactive ion and functions in

many enzymatic biochemical processes. Iron is a transition metal (number 26 on the periodic table) with an atomic weight of 55.8. It is the second most prevalent metal and the fourth most abundant element in the Earth’s crust.

Iron has interesting and unique properties related to its absorption, distribution, and elimination. Intestinal iron absorption is a complex and active process that occurs mostly in the proximal small intestine [6]. Most dietary inorganic iron is in the ferric (Fe³⁺) form. Iron in the gut lumen may form complexes with other constituents, forming insoluble nonbioavailable products. Mucin, at the cell surface of the enterocyte, binds iron, preparing it for integrin-mediated systemic absorption. Mobilferrin binds the iron within the enterocyte cytoplasm. Iron eventually is transferred to paraferitin and ferritin before entering the bloodstream complexed to transferrin. Because the proportion of iron absorbed decreases with increasing dose [7], an overdosed patient absorbs disproportionately less of the dose ingested than the amount absorbed when iron is given therapeutically. In healthy adults, 2–10% of dietary iron eventually is absorbed. A canine model showed that only 14% of a fatal oral dose of ferrous sulfate was absorbed [8]. In contrast, people with iron deficiency may absorb 80–90% of an oral dose [9].

After oral ingestion, iron either remains in the gut mucosa and eventually is excreted in the stool or is transported in the blood by transferrin primarily to the bone marrow for hemoglobin synthesis. The liver differs from the rest of the body, including the placenta, in that its capacity for iron uptake is unlimited [10, 11]. This first-pass effect is chiefly responsible for the decrease in plasma iron concentration after ingestion. These concepts support early iron concentration determination – 4–6 h after ingestion – as being useful after overdose, followed by the use of clinical parameters to predict prognosis after 8–12 h.

Pharmacokinetics of Iron
<i>Volume of distribution:</i> preparation dependent
<i>Protein binding:</i> 99%
<i>Mechanisms of clearance:</i> renal, fecal, skin desquamation
<i>Active metabolites:</i> none
<i>Method to enhance clearance:</i> deferoxamine

Table 1 Iron content of common preparations

Preparation	Elemental iron (%)
Ferrous gluconate	12
Ferrous sulfate ^a	20
Ferric chloride ^a	20
Ferrous chloride	28
Ferrous fumarate	33

^aHydrated

Total iron body stores are approximately 3–4 g in adults, with 70% distributed in hemoglobin in the ferrous (Fe²⁺) state. It is also present in ferritin and hemosiderin, which are stored in the liver, spleen, and bone marrow. About 1–2 mg of iron is eliminated daily through urinary and fecal excretion and skin desquamation. The usually recommended daily allowance of iron is 10 mg in men, 18 mg in women, and 30–60 mg in women during pregnancy and lactation.

The amount of elemental iron ingested is the key factor in predicting the severity of toxicity. Common preparations contain various percentages of elemental iron (Table 1). Although 20 mg/kg of elemental iron or less may result in gastric upset, potentially severe toxicity may follow ingestions of 40–60 mg/kg, and potentially lethal doses range from 200–250 mg/kg [12]. In toddlers, doses of 1.0 g of elemental iron have been reported to be fatal [13, 14].

Pathophysiology

Iron, an essential element for bodily functions, must come from exogenous sources. It functions as a catalyst for the Haber–Weiss reaction resulting in the generation of a highly reactive hydroxyl radical:

Iron-induced lipid peroxidation, resulting from the production of these free radicals, is the primary mechanism of iron poisoning [15, 16]. These free radicals induce local injury, most notably in locations of high iron concentrations, such

as the intestine and liver. The primary intracellular target of toxicity is the mitochondria, resulting in destruction of cristae and loss of respiratory enzyme activity in a manner that is consistent with suppression of cellular respiration, without uncoupling oxidative phosphorylation [17, 18]. Iron primarily affects the gastrointestinal (GI) tract, liver, cardiovascular system, and acid–base status of the poisoned patient. Because of the high metabolic activity of the heart, the myocardial mitochondria are particularly vulnerable to the toxic effects of iron poisoning.

Gastrointestinal

The initial GI symptoms after iron overdose are due to a direct local irritant effect. With large ingestions, free radical-induced lipid peroxidation causes secondary injury to the GI tract. There is a significant risk of hemorrhage and ulcerative damage from segmental gut infarction in children and adults [19]. Because of this damage, there is a concern for emerging GI bleeding during the first 48–72 h after ingestion. Delayed effects, classically stricture formation, may occur weeks after exposure. Gastric outlet obstruction occurring 2–4 weeks post exposure is a consequence of healing and scarring of the gut. A high index of suspicion for gastric outlet obstruction exists in patients who have continual vomiting 2–3 weeks after the exposure incident or an onset of emesis after a symptom-free period [20]. Although pyloric injury is most common, lesions may occur at any location in the gut [19].

Hepatic

Characteristic hemorrhagic hepatic periportal necrosis has been described in autopsy reports of patients who died from iron poisoning and in experimental animal models [21]. Other reports indicate similar damage in patients and animal models [22]. After absorption, iron is transported to the liver via the portal vein, where carrier-mediated uptake into zone 1 acinar cells eventually becomes overwhelmed. Microscopic

observations indicate that hepatic mitochondrial injury within zone 1 is the primary location and mechanism of toxicity [23]. Because liver cell regeneration is a zone 1 function, injury to this region is of particular significance. After this injury, acute hepatic failure with elevated hepatic transaminases and serum ammonia concentrations, jaundice, steatosis, and hepatic coma may occur [24].

Coagulopathy

Coagulopathy resulting from severe iron poisoning is characteristically biphasic [25]. A dose-related reversible coagulopathy has been demonstrated in a canine model and in humans [25]. This condition results from a transient, early, dose-dependent depression of coagulation factors V, VII, IX, and X, causing a prolongation of the partial thromboplastin time [25]. An *in vitro* study revealed that free iron may inhibit the formation of thrombin and subsequently thrombin's ability to form fibrin from fibrinogen [26]. This early coagulopathy may subside as iron levels decrease; however, severe poisoning may result in a second phase (2–7 days postingestion) of progressive dysfunction of coagulation secondary to hepatotoxicity.

Cardiovascular

Circulatory shock is the most common cause of death after severe iron poisoning. In addition to hypovolemia resulting from GI volume loss and hemorrhage, an early distributive shock has been shown in animal models [27, 28]. The myocardium has high metabolic activity, and acute iron-induced cardiotoxicity may be mediated by free radical generation [29]. In addition to interference with mitochondrial adenosine triphosphate production, membrane lipid peroxidation may interfere directly with slow-channel calcium exchange or the activity of the sarcoplasmic reticulum [30]. Diminished myocardial contractility is an important component of the pathogenesis of iron-induced shock [31]. Cardiac failure may

occur 1 to several days after a major iron overdose [32]. The pathophysiology of shock resulting from iron overdose is therefore multifactorial.

Metabolic

Metabolic acidosis is a prominent feature of iron poisoning. As discussed earlier, circulatory shock is one pathophysiologic mechanism responsible for this metabolic acidosis. Acidosis also may occur, however, in the absence of cardiovascular instability [33]. As described previously, iron poisoning suppresses cellular respiration. A principal mechanism by which iron causes a metabolic acidosis occurs, however, after absorption of a quantity of iron that exceeds the binding capacity of transferrin. When unbound iron is present, its hydrolysis liberates three unbuffered protons from each ferric ion [34]:

Other Pathophysiologic Effects

Altered mental status may occur after large ingestions and is presumably multifactorial and related to the factors described earlier. Although no major direct toxicity is clinically apparent and relevant to the central nervous system, kidney, lung, and spleen, autopsy studies have revealed elevated iron concentrations in these organ systems and in the stomach, liver, and small intestine [35].

Clinical Presentation and Life-Threatening Complications

Classically, iron poisoning is described as occurring in five clinical stages (Table 2). Not all patients manifest this “textbook” presentation after overdose, however, and there is the potential for considerable temporal variability and overlap among these stages. The severity and stage of a particular patient’s poisoning should be determined by his or her individual clinical evaluation, not simply by the number of hours postingestion.

Table 2 Stages of iron poisoning

Stage	Typical
I – Gastrointestinal	30 min–6 h
II – Quiescent	2–8 h
III – Shock	2–48 h
IV – Hepatotoxicity	12–24 h
V – Gut obstruction	1–7 weeks

Stage I (the GI stage) of poisoning is encountered almost universally in all patients after significant iron ingestion. Epigastric pain, nausea, vomiting, and diarrhea typically occur immediately after ingestion in cases of overdose [36]. Hypotension, pallor, and lethargy often occur, resulting from vasodilation, intravascular volume loss, gastroenteritis, hematemesis, melena, or hematochezia secondary to the local effects of iron on the gut mucosa. Metabolic acidosis may occur at this stage. If acidosis is significant, blood volume loss occurs, resulting in circulatory shock, and the patient may progress directly into stage III.

Stage II is the time period associated with iron poisoning that is described as the latent or *quiescent* phase. During this interval, which may begin several hours postingestion, the patient is in transition between the resolution of direct GI signs and symptoms and the appearance of overt systemic toxicity. This often-described quiescent phase may reflect failure to recognize ongoing clinical toxicity. The patient may have fewer overt GI manifestations during this time, lulling the clinician into an underestimation of the true seriousness of the ingestion [12]. During this apparently clinically benign period, however, patients may have a worsening metabolic acidosis if volume resuscitation is not sufficient to restore adequate tissue perfusion. Patients who progress through stage I with resolution of clinical manifestations and without development of a metabolic acidosis are unlikely to develop more serious systemic iron toxicity.

Stage III, the shock stage of iron toxicity, is defined by evidence of insufficient tissue perfusion and shock and typically becomes manifest at least several hours after ingestion. Most deaths due to iron poisoning occur in this stage. Multiple

organ dysfunction as a result of cellular toxicity and inadequate perfusion may result in hypotension, tachycardia, altered mental status, seizures, coma, worsening metabolic acidosis, renal failure, hepatic dysfunction, coagulopathy, myocardial depression, pulmonary edema, and mesenteric ischemia [37]. Hepatotoxicity often is evident during stage III; however, this may also occur without concomitant shock.

Stage IV (hepatotoxicity) is not a universal finding in iron-poisoned patients [38]. The onset of this stage typically occurs 12–24 h post-ingestion but may occur 2–3 days after overdose [24]. Hepatic dysfunction is a poor prognostic sign when present [25], with hemorrhage secondary to coagulopathy often contributing to patient demise [25].

The hallmark of stage V is gastric outlet obstruction; however, fortunately this stage rarely occurs [12]. Local mucosal injury may lead to development of stricture formation several weeks postingestion [19]. Although the classic site of obstruction is the pylorus, segmental injury may occur along the length of the gut [19]. The diagnosis of gastric outlet obstruction should be considered in patients with persistent vomiting, achlorhydria, abdominal pain, and distention more than 1 week postingestion.

Iron poisoning may present in any of the abovementioned discrete stages, may skip specific stages, or may reflect overlap between or among different stages. The stages of toxicity are used as a guide to the conceptualization of the natural course of iron poisoning rather than as a consistently predictable sequence of events.

Diagnosis

The diagnosis of iron toxicity may be evident based on a history of ingestion and corresponding signs of iron toxicity. Any pediatric ingestion over 40 mg/kg (or 6.5 ml syrup/kg) should be assessed for iron toxicity. GI symptoms are present within 1 hr of ingestion in virtually all patients with significant iron ingestions [39]. Tachycardia may also be an early sign of iron toxicity. If no history of iron ingestion is

offered, however, the differential diagnosis includes other medical and surgical reasons for the varied manifestations of iron poisoning. Other poisonings to consider include those involving mercuric chloride, salicylates, pesticides, arsenic, and colchicine.

All patients with known or suspected iron overdose should receive an X-ray of the abdomen to evaluate for radiopaque tablets [40, 41]. Large overdoses of tablets can be visualized in the GI tract, helping to verify historical features and guide management with GI decontamination. If the patient ingested a liquid preparation, the abdominal film typically is unrevealing [41]. Pediatric multivitamins containing iron have such a low iron content that X-rays after ingestion of these also typically are negative [42]. Clinically significant poisoning after ingestion of iron-containing multivitamins is virtually nonexistent [43]. Negative abdominal plain films after iron ingestion also may be explained by dissolution of an ingested solid formulation; this is especially true in patients who present late after ingestion.

We recommend that a serum iron concentration be obtained on presentation and then every 1–2 h to monitor the symptomatic patient further. When a clear downward trend of serum iron concentrations is established, it is no longer necessary to follow this parameter. Iron concentrations less than 500 µg/dL (<90 µmol/L) at 4–6 h postingestion typically are not associated with significant systemic toxicity [44, 45]. Systemic toxicity often is seen with iron concentrations of 500–1000 µg/dL (90–180 µmol/L), with levels greater than 1000 µg/dL (>180 µmol/L) being associated with severe life-threatening illness.

A high anion gap metabolic acidosis accompanying an elevated lactate concentration should be assumed to be an indication of serious toxicity from iron ingestion [37] and the need for chelation therapy. Because of the possibility of hemorrhage and multiple-organ toxicity, a complete blood count, hepatic and renal function tests, electrolytes, and coagulation profile should be obtained. The presence of hemorrhage or anemia should prompt preparation for possible blood product replacement.

Historically, other laboratory findings, such as leukocytosis (white blood cell count $>15,000/\text{mm}^3$) and hyperglycemia (serum glucose $>150 \text{ mg/dL}$ [8.25 mmol/L]), were used as indices of severity of iron poisoning [46]. These parameters have not been shown to be sensitive predictors of toxicity, however [44, 47]. Likewise, a serum iron concentration greater than the total iron-binding capacity, previously considered an indication for chelation therapy, has not been found to be a reliable index of toxicity and no longer is recommended [44, 48, 49].

Indications for ICU Admission in Iron Poisoning

Significant acidemia (arterial pH < 7.3)

Shock/neurodynamic compromise

Altered mental status

Gastrointestinal hemorrhage

Serum iron concentration $>500 \text{ }\mu\text{g/dL}$ ($90 \text{ }\mu\text{mol/L}$)

Radiologic evidence of a significant gastrointestinal burden of iron ($>50 \text{ mg}$ of elemental iron/kg)

Deferoxamine administration

Significant hepatic dysfunction

Treatment

Patients with significant iron ingestions or severe systemic toxicity warrant monitoring in the intensive care unit. Secure intravenous access, fluid volume replacement, oxygen supplementation, cardiac monitoring, and airway and ventilatory support are essential to the initial management of the critically iron-poisoned patient. Bedside ultrasound of the heart and inferior vena cava or even a Swan–Ganz catheter may be indicated for monitoring of hemodynamic parameters during treatment and to differentiate between cardiogenic and distributive shock.

Limiting the absorption of ingested iron should be considered during initial management. Gastric lavage is an alternative form of gastric emptying. This procedure also has serious risks, has not proved to change outcome after iron ingestion, and should be considered only in life-threatening ingestions presenting within 1 h [50, 52]. Even in these circumstances, the efficacy of gastric lavage is questionable. Activated charcoal has not been shown to be effective in adsorbing iron [53]. Consideration of activated charcoal is appropriate when coingestion of noniron products has occurred. However, activated charcoal has not been shown to alter the outcome in poisoned patients. It may decrease drug absorption if given within 1 hr of ingestion.

The mainstay of GI decontamination for iron poisoning generally is considered to be whole-bowel irrigation [54, 55] (Grade III evidence). This procedure has not been shown, however, to alter the clinical course or outcome of iron-poisoned patients [54]. Whole-bowel irrigation theoretically is important only in patients with abdominal radiographs revealing substantial numbers of radiopaque iron tablets. Whole-bowel irrigation is reviewed in ► [Chap. 3, “Therapeutic Approach to the Critically Poisoned Patient.”](#) Although whole-bowel irrigation usually is limited to several hours of administration, one case report of multiple iron tablet persistence in the gut described a 5-day course of whole-bowel irrigation [56]. This case also may be taken as evidence, however, of the lack of efficacy of this technique. Subsequent abdominal X-rays can help guide the clearance of iron from the gut.

Gastroenterologic or surgical consultation may be warranted if a concretion or bezoar is shown or suspected; this is unusual, however. Concretions may be present when iron levels continue to rise. Usually there is a downward trend toward clearing by 6–24 h postingestion. Several authors reported successful gastrotomy and removal of massive amounts of iron tablets not amenable to removal by less invasive measures [57–61]. Clinical evidence of bowel obstruction may indicate intestinal necrosis. Lifesaving small-bowel resection was performed 24 h after presentation in a patient with a distended abdomen and signs of peritonitis [62].

Other attempts at reducing iron absorption from the gut have been undertaken without success. Oral bicarbonate, phosphate, and magnesium hydroxide have been used with the idea that if they formed insoluble complexes with iron, this would decrease absorption. Except for one canine study, data from in vitro and in vivo studies do not support bicarbonate or phosphate use, and these treatments may result in severe electrolyte imbalances [63–66]. Animal and human volunteer studies revealed a reduction in iron absorption after the administration of magnesium hydroxide; however, it does not affect absorption in humans after large overdoses of iron [67–69]. At present, there are insufficient data to support routine use of these modalities in human iron poisoning. Oral deferoxamine was shown in one prospective human study to reduce GI absorption of ferrous sulfate when mixed as a slurry with activated charcoal. Ferrioxamine, the deferoxamine–iron complex, has been shown to be lethal in animals after it is absorbed, but ferrioxamine absorption is reduced when activated charcoal is coadministered with deferoxamine [70, 71]. Because of the concerns about the toxicity of ferrioxamine, oral deferoxamine is not recommended.

Iron-induced hepatotoxicity should be regarded as a marker of severe toxicity. Because the periportal area is most affected, iron-induced hepatotoxicity portends a much poorer overall prognosis than similar insults caused by other toxicants [22]. In light of this, hepatic monitoring and treatment of organ failure or coagulopathy are indicated. Profound liver dysfunction warrants surgical consultation for possible transplantation. Correction of electrolyte and glucose abnormalities also may be crucial to patient outcome.

Hemodialysis should be used on a supportive basis for acute renal failure, usually developing in response to circulatory shock. Iron is not amenable to hemodialysis, even though the iron–deferoxamine complex can be cleared in this manner [72, 73].

Deferoxamine, derived from *Streptomyces pilosus*, is the specific chelator of choice for iron

poisoning. After complexing with free iron (iron not found in hemoglobin, myoglobin, ferritin, or transferrin), it forms ferrioxamine, which is excreted in the urine [3]. Deferoxamine also has been shown to promote clearance of intracellular iron effectively. Ferrioxamine produces a reddish-brown or “vin rose” appearance to the urine [74]. Deferoxamine challenge tests have been used in the past as a marker of iron excretion, as indicated by this urine color change. This test no longer is recommended; however, it is one may observe a urine sample before treatment and follow the course of color change during chelation. A total of 100 mg of deferoxamine mesylate chelates only approximately 8.5 mg of ferric iron. Although the use of deferoxamine in severe iron poisoning is considered the standard of care, there are no published controlled studies that show a change in outcome with this treatment [75, 76] (Grade III evidence).

Deferoxamine treatment should be administered as early as possible after poisoning. Although not formally validated, the data reviewed earlier in this chapter that suggest logical indications for deferoxamine treatment are indications of moderate-to-severe systemic toxicity, such as shock, GI bleeding, lethargy, and central nervous system depression. Metabolic acidosis is a reliable marker of cellular iron toxicity [37] and therefore should be considered to be an indication for initiating treatment. There is no rationale for withholding chelation while waiting for a serum iron concentration in significantly poisoned patients. An iron level 4–6 h postingestion of equal to or greater than 500 µg/dL (≥ 90 µmol/L) also is considered to be an indication for treatment [44, 45] (Grade III recommendation). After 12 h, the serum iron concentration is of no practical significance because the systemic burden has been distributed from the vascular compartment into tissues.

Recommendations for deferoxamine dosing are based primarily on case reports and have been established arbitrarily [76]. The intravenous route of administration is preferred. Intramuscular administration was used previously for less severe poisoning, but it is not reliable. Titration of the intravenous infusion up to a rate of 15 mg/kg/h

should be initiated while the patient is carefully monitored for adverse effects, including rate-related hypotension [77, 78]. Histamine release may underlie the hypotension and the flushing and urticaria that may be observed during deferoxamine infusion [78]. Administration of deferoxamine at even higher rates has been shown to be safe in ill patients and in patients on long-term hemodialysis [79]. There have been recommendations to administer less than 6–8 g/day even though 16 g/day has been given without concomitant side effects [80]. It is vital to maintain adequate intravenous fluid volume replacement during deferoxamine therapy to protect against the development of acute renal failure [81]. Finally, continuous infusions for greater than 24 h have been reported to be associated with adult respiratory distress syndrome; however, this interpretation is confounded by the presence of adult respiratory distress syndrome in severe iron poisoning, even in untreated cases [82–84]. A reasonable end point of therapy is cessation of anion gap metabolic acidosis and resolution of systemic toxicity. Because the deferoxamine–iron complex acts as a siderophore for the growth of *Yersinia enterocolitica*, sepsis after chelation therapy is a risk, and appropriate antimicrobial therapy should be initiated if high-grade fever, diarrhea, or signs of peritonitis develop. Appropriate antibiotics include aminoglycosides, trimethoprim–sulfamethoxazole, third-generation cephalosporins, doxycycline, or fluoroquinolones. If abscesses occur, they will require surgical drainage. Chelation therapy should not be suspended during antibiotic therapy [85–87]. It is important to determine serum iron concentrations by atomic absorption spectroscopy in deferoxamine-treated patients because deferoxamine interferes with most other routine assays.

Criteria for ICU Discharge in Iron Poisoning

Absence of acidemia or other systemic disorders (e.g., coagulopathy)
Hemodynamic stability
Clear sensorium
Declining serum iron concentrations

Special Populations

Pregnant Patients

Iron overdose has occurred with relative frequency in pregnant patients [88]. There is no proven teratogenic risk of deferoxamine therapy during pregnancy, and fetal loss may occur as a result of severe maternal iron toxicity. Similar to trauma and many other diseases of pregnant women, the goals are to stabilize and treat the mother, which stabilizes and treats the fetus. The approach to a pregnant patient is no different from that for any other patient; other than that if the fetus is potentially viable, it should be monitored for distress. Although spontaneous abortion, preterm delivery, and malformations are potential sequelae of treatment in severe iron poisoning, several cases reported successful use of deferoxamine in pregnancy [89–92]. Whole-bowel irrigation has been used successfully in the first trimester to treat an iron overdose [93]. One report described a postnatal fatality in a 30-year-old woman who was treated with deferoxamine 1 day after ingestion and successfully delivered a healthy infant 2 weeks before experiencing lethal multiple organ dysfunction [94]. The placenta serves as the fetus's barrier to systemic iron overload and associated toxicity. This concept is supported in an ovine model [11]. Deferoxamine may cross the placenta when the mother is treated for toxicity [89]. Harm to the fetus from deferoxamine use in pregnancy is referenced [11, 91] yet not supported by the actual evidence. Cases describe first-trimester use of deferoxamine in women with chronic overload without subsequent fetal abnormalities [95, 96]. Based on this deferoxamine therapy should not be withheld out of concern for the fetus. Appropriately treating the mother is tantamount to treating the fetus.

Parenteral Iron Infusions

Intravenous iron therapy is indicated in patients who (1) are hemodialysis dependent with iron

deficiency anemia, (2) have gastrointestinal mal-
adies such as Crohn's disease or a history of
gastric resection or bypass, or (3) are losing iron
from blood sources at higher rates than oral iron
can be tolerated. While isolated parenteral iron
toxicity requiring deferoxamine therapy is not
reported, iron infusions can result in infusion
reactions. Infusion reactions are considered
hypersensitivity reactions and patients at risk
include previous reactions, rapid infusion
rates, multiple drug reactions, severe atopy, and
possibly severe inflammatory diseases [97].
There exists controversy whether or not
these reactions are always true IgE mediated in
all cases. Iron dextran has historically thought to
be linked to anaphylactoid reactions compared
to iron gluconate and sucrose [98]. Complement
activation-related pseudo-allergy triggered
by iron nanoparticles is probably a more frequent
pathogenetic mechanism in acute reactions
to current formulations of intravenous iron
than is an immunological IgE-mediated
response [97].

Management of these reactions is therefore
recognition and discontinuation of the infusion.
Current consensus would still recommend intra-
venous fluids and corticosteroids for moderate
reactions and potentially supplemental oxygen,
epinephrine, and a nebulized beta-2 agonist for
more severe reactions [99].

Common Errors in Iron Poisoning

Withholding deferoxamine in an ill
patient while waiting for a serum iron
concentration

Withholding deferoxamine in a pregnant
patient who meets criteria for treatment

Assessing a patient in stage II of toxicity as
improved or fully recovered

Relying on leukocytosis and hyperglyce-
mia to predict prognosis or guide therapy

Using total iron-binding capacity or a chela-
tion challenge test to indicate need for
deferoxamine

Administering deferoxamine to patients
who exhibit only direct gastrointestinal toxicity

Key Points in Iron Poisoning

1. Estimate total iron ingested based on the elemental dose and not the weight of the salt.
2. Serum iron concentrations beyond 12 h after ingestion are of no benefit.
3. The end point of deferoxamine therapy is guided best by clinical stability of the patient and cessation of acidemia.
4. Fluid hydration is crucial during deferoxamine administration to help prevent acute renal failure.
5. Pregnant patients are approached in the same way and aggressively as nonpregnant patients.

In the 1920s, a hemorrhagic disorder of cattle feeding on spoiled clover silage was recognized. Studies of “sweet clover disease” led to the isolation in 1939 of dicumarol (bishydroxycoumarin), the first oral anticoagulant drug. A more potent synthetic derivative, 3-(α -acetonylbenzyl)-4-hydroxycoumarin, was produced in 1948 and named warfarin, after the Wisconsin Alumni Research Foundation. Warfarin initially was used mostly as a rodenticide because of concerns of unacceptable toxicity. Then in 1951, an army inductee uneventfully survived a massive overdose of a warfarin rodenticide. Warfarin also was used to treat President Eisenhower after a heart attack in 1955, contributing to its general acceptance as a therapeutic drug. Although not used in the United States, phenprocoumon (Fig. 1) and acenocoumarol are used in other parts of the world. These three drugs are 4-hydroxycoumarin derivatives with nonpolar carbon substituents at the 3 position. Indane-1,3-dione oral anticoagulants are available but are used infrequently therapeutically. Many rat populations have become resistant to warfarin, leading to the use of “superwarfarins” (see ► Chap. 95, “Rodenticides”) since the 1970s. These rodenticides have higher potencies and considerably longer half-lives than warfarin and the other therapeutic vitamin K antagonists (VKA).

Recently, several novel oral anticoagulants (NOACs) have been developed. These include direct activated factor Xa inhibitors (apixaban, edoxaban, rivaroxaban) and the direct

thrombin (II) inhibitor dabigatran. These anticoagulants are prescribed with fixed dosing and do not need regular monitoring. They are marketed to have improved characteristics including less food and drug interactions, faster onset of action, and shorter half-lives of elimination.

Pharmacokinetics

The pharmacokinetics of available oral anticoagulants are listed in Table 1 [1–6]. S-Warfarin, the more potent enantiomer, undergoes metabolism by cytochrome P-450 2C9 (CYP2C9), with an elimination half-life ranging from 0.5 to 3 days. CYP2C9 and vitamin K epoxide reductase subunit 1 polymorphisms explain the variation in half-life and individual sensitivities to warfarin doses

required to reach therapeutic anticoagulation [1, 2]. Apixaban, rivaroxaban, and edoxaban are substrates of p-glycoprotein; edoxaban and dabigatran have active metabolites. Most of the NOACs are primarily renally eliminated.

Pathophysiology

Vitamin K Antagonists

Warfarin and other vitamin K antagonists interfere with the production of functional clotting factors. The vitamin K-dependent factors (factors II, VII, IX, and X and the anticoagulant factors protein C and protein S) undergo post-translational γ -carboxylation at several glutamate residues, necessary for binding calcium

Table 1 Pharmacokinetics of oral anticoagulants

Vitamin K antagonists					
	Tmax (hrs)	Protein binding (%)	Volume of distribution	Metabolism	Mechanism of elimination, half-life (hrs)
Warfarin	2–8	99	0.14 L/kg	CYP2C9	Renal, 0.5–3 days
Direct Xa inhibitors					
Apixaban	1.5–4	87	21–61 L	CYP3A4	Fecal/renal, 6.8–12
Edoxaban	1–2	55	107 L	Minimal hepatic	Bile/renal, 5.5–10.5

Direct thrombin (IIa) inhibitor					
Dabigatran	1–6	35	50–70 L	Hepatic	Renal, 12–17

Fig. 2 Mechanism of action of the oral anticoagulants

ions involved in establishing a functional clotting cascade. This carboxylation step oxidizes the fully reduced, active vitamin K₁ (vitamin K hydroquinone) to vitamin K₁ 2,3-epoxide (Fig. 2). Regenerating the active form of vitamin K occurs continuously in normal subjects. The epoxide first is reduced to a quinone, then to the

hydroquinone; both of these reducing steps are inhibited by warfarin. Supplemental vitamin K₁ can be administered and is metabolized to the hydroquinone form in a reduced nicotinamide adenine dinucleotide phosphate-dependent step not inhibited by anticoagulants, resulting in active clotting factor synthesis. In the presence

Fig. 3 Coagulation cascade (a = active form)

of warfarin, however, the inactive, epoxide form of vitamin K accumulates and cannot be reduced to the active form.

Novel Oral Anticoagulants

Unlike warfarin, which interferes with coagulation factor production, the NOACs disrupt clotting further down the coagulation cascade, primarily interfering with thrombus formation. Apixaban, edoxaban, and rivaroxaban selectively inhibit activated clotting factor Xa, decreasing activation of prothrombin to thrombin. Prothrombinase activity is also inhibited. Dabigatran and its active metabolites, acyl glucuronides, are competitive direct inhibitors of thrombin, inhibiting both free and clot-bound thrombin as well as thrombin-induced platelet aggregation (Fig. 3).

Clinical Presentation, Diagnosis, and Treatment

Vitamin K Antagonists

Chronic Toxicity

Most articles about warfarin “overdose” actually refer to chronic, often asymptomatic, supratherapeutic dosing and not to acute, intentional ingestions. As expected, the worse the coagulopathy, the higher the risk. In all patients taking warfarin for therapeutic purposes, the overall frequency of bleeding is 7.6 to 16.5 events per 100 patient-years, and frequency of major or life-threatening bleeds is 1.3 to 2.7 events per 100 patient years. The risk of an acute bleeding event within a 48-h period increases from 1 in 4000, for an international

normalized ratio (INR) between 2 and 2.9, to 1 in 100, for an INR of 7 or greater [7]. Gastrointestinal bleeding is the most common type, whereas intracranial bleeding carries the highest risk of mortality.

Indications for ICU Admission in All Oral**Anticoagulant Poisoning**

Oral anticoagulant-induced coagulopathy associated with

Intracranial hemorrhage

Gastrointestinal hemorrhage

Other clinically significant bleeding

Intentional overdose of oral anticoagulant drugs

The ideal management of chronic warfarin toxicity is unclear because most studies have been retrospective, have been of poor quality, and have had interstudy variance in treatment groups and doses. Notwithstanding these limitations, the American College of Chest Physicians (ACCP) has published consensus treatment guidelines [8, 9]. Over the last several years, similar guidelines have recommended conservative treatment of overanticoagulated patients, with less reliance on active interventions in stable patients [10]. However, compliance with these guidelines are varied [11].

According to ACCP guidelines, in the absence of clinically significant bleeding, patients with an INR less than 5 should have warfarin withheld and resumed when a therapeutic INR is reached. For INR values of 5–9, warfarin is held for one or two doses and resumed when a therapeutic INR is achieved or warfarin is held for one dose and 1 to 2.5 mg vitamin K₁ (phytonadione) is given orally. When an INR is greater than 9, warfarin is held and the patient is given 3–5 mg of vitamin K₁ orally. Twenty-four hours after vitamin K₁ is given by any route to patients with asymptomatic coagulopathy after chronic, therapeutic dosing, the reduction in INR is comparable: 47–86% for oral administration, 25–67% for subcutaneous administration, 40–75% for intravenous administration versus only 21–42% for simply discontinuing warfarin [12]. At 48 h, INR

reduction was similar for vitamin K doses greater than 2 mg for both oral and intravenous administration [13].

The American College of Chest Physicians recommendations are more aggressive when rapid reversal of coagulopathy is indicated. These recommendations specify that if surgery is planned and the INR is between 5 and 9, warfarin should be held and the patient given 2–4 mg of vitamin K₁ orally about 24 h before the procedure. Additional vitamin K₁, 1–2 mg orally, may be given if necessary. If the INR is greater than 20 or the patient is experiencing serious bleeding, vitamin K₁, 10 mg, should be given by slow intravenous infusion and may be repeated every 12 h as needed. If immediate reversal of coagulopathy is indicated (e.g., intracranial bleed, hemodynamically significant gastrointestinal hemorrhage), intravenous infusion of four-factor prothrombin complex concentrate or fresh frozen plasma is indicated. Warfarin resistance can be induced by administering excessive vitamin K₁, and patients may require heparinization temporarily if continued therapeutic anticoagulation is desired.

Criteria for ICU Discharge in Oral VKA Poisoning

Absence of clinically significant bleeding

Laboratory values stable for at least 12 (preferably 24) hours

Prothrombin time/international normalized ratio

Hemoglobin

Acute Overdose

In the absence of a positive or suggestive history, evidence supporting the diagnosis of warfarin overdose is summarized in Table 2. Since warfarin is not detected by most commonly used urine or plasma drug screens, elevations in prothrombin times should be a significant clue. However, peak elevations in prothrombin times will be delayed after acute overdose [14]. Patients not chronically anticoagulated typically exhibit a rise in the INR more than 12 h after ingestion, earliest

Table 2 Diagnostic clues to oral VKA overdose

Prolongation of prothrombin time out of proportion to activated partial thromboplastin time (both may be unmeasurable in severe overdoses)
Coagulopathy that responds, at least temporarily, to vitamin K ₁
Selective decreased activity of vitamin K-dependent factors – factors II, VII, IX, and X; protein C; and protein S (antigenic levels should be normal)

at 16 h [15]. Treatment of warfarin toxicity should be easier than for the anticoagulant rodenticides, mostly owing to their shorter half-lives. Patients who have intentionally ingested long-acting superwarfarins may require doses of vitamin K of 100 mg for as long as 6 months [16] (Grade III recommendation). In contrast, most patients with acute warfarin overdose require less than 1 week of therapy [17].

Reported treatments for acute warfarin overdose are varied. An asymptomatic toddler who ingested 45 to 50 mg warfarin sodium 20 min earlier was treated with activated charcoal and daily prothrombin time monitoring [14]. When the prothrombin time increased from 11.8 s (baseline) to 18 s on day 3, the toddler was given 2.5 mg of intramuscular vitamin K₁ daily for 3 days. It is debatable whether this treatment was necessary, because no bleeding complications occurred. Administering vitamin K when not clinically indicated may impair the ability to accurately follow the degree of anticoagulation. Adults with acute VKA overdoses typically present after coagulopathy has developed. Various coagulation products in addition to vitamin K have been used when urgent/emergent warfarin reversal is needed. A man presenting with bruising, gingival bleeding, and hematuria 1 day after ingesting 2000 mg of warfarin and injecting 250,000 units of heparin subcutaneously was treated successfully with intravenous prothrombin complex concentrate and several 20-mg intravenous doses of vitamin K [18]. Other cases of acute warfarin overdose have been managed with infusions of fresh frozen plasma, which seems especially helpful in cases in which maintaining therapeutic anticoagulation

is desirable [19]. A comparison of outcomes in patients requiring urgent warfarin reversal found that four-factor PCC had a faster reversal with lower red blood cell transfusion requirements and fewer adverse events than frozen plasma [20]. (Grade II-3 evidence)

Oral activated charcoal can be considered in patients presenting within an hour after acute warfarin ingestion based on the theoretical possibility of reducing drug absorption. While this treatment may decrease warfarin absorption, there are no data indicating that such therapy alters outcome in these patients. Acute gastrointestinal bleeding is a relative contraindication to charcoal because it may obscure endoscopic evaluation. Oral cholestyramine may increase clearance by interrupting enterohepatic circulation (Grade III evidence). Cholestyramine (4 g three times a day) reduced the half-life of single-dose intravenous warfarin from 1.98 ± 0.48 days to 1.34 ± 0.46 days ($P < 0.001$) in human volunteers [21]. In a case report of oral warfarin overdose, cholestyramine (4 g four times a day) decreased warfarin elimination half-life from 53 h to 33 h [22]. While it may decrease elimination half-life and can be considered for treatment after acute overdose, it has not been shown to decrease bleeding risk or decrease hospital length of stay.

Key Points in the Management of Acute VKA Overdose

1. Prothrombin time peaks in 0.5–4.5 days – do not be falsely reassured by minimal prothrombin time prolongation early after ingestion.
2. Gastrointestinal decontamination with activated charcoal or cholestyramine may be beneficial.
3. Vitamin K orally or intravenously reverses coagulopathy; dosing every 4–8 h may be required (in contrast to treating excessive coagulopathy after therapeutic doses).
4. Four-factor prothrombin complex concentrates (50 IU/kg), if unavailable then Fresh frozen plasma (15 mL/kg), should be used to treat potentially life-threatening bleeding – may need to be repeated.

Novel Oral Anticoagulants

Acute overdoses of NOACs are rarely reported and clinical experience is limited. In a review of dabigatran exposures reported to regional poison centers, severe outcomes from dabigatran exposures were not common, occurring in approximately 5% of cases [23]. Another single poison center review of dabigatran and rivaroxaban exposures demonstrated acute massive self-harm ingestions can lead to abnormal coagulation studies but only mild bleeding. Low-dose ingestions and pediatric ingestions were unlikely to lead to adverse effects, and significant hemorrhage only occurred in chronic therapeutic dosing [24]. A meta-analysis evaluated risk factors for bleeding with NOACs and identified that the highest risk factors were age and concomitant use of antiplatelet drug therapy [25]. Additionally, renal impairment in elderly patients has been identified as a risk factor for bleeding on dabigatran [26]. Reported adverse effects to many of the NOACs are GI upset, gastritis, and gastrointestinal bleeding. Dabigatran contains tartaric acid which can lead to dyspepsia and gastritis. Initial clinical trials of direct Xa inhibitors and thrombin inhibitors demonstrated dabigatran had an increased risk for GI bleeding when compared to warfarin (overall RR of 1.28, CI 1.05–1.56) [27]. Conversely, subsequent retrospective cohort reviews did not find an increased risk of GI bleed except in patients over 65 years of age, renal or cardiovascular comorbidities, previous *H. pylori* infections, alcohol use, antiplatelet therapy, and digoxin use [28, 29].

Although there are many pro-hemostatic products available in the event of an acute hemorrhage, unfortunately none of them have clearly been shown to completely reverse anticoagulation or change morbidity or mortality associated from a bleed attributed to the NOACs.

Direct Xa Inhibitors

Unlike warfarin, there are no readily available commercial laboratory coagulation values that can accurately assess the degree of anticoagulation for the NOACs. For most direct Xa inhibitors, partial thromboplastin time (PTT)

will not be significantly affected or will have variability between assays. Prothrombin time (PT) can be used as a qualitative measurement for rivaroxaban and the other Xa inhibitors but poorly reflects the intensity of anticoagulation [27]. Chromogenic antifactor Xa assays were initially designed for indirect, antithrombin-dependent factor Xa inhibitors (heparins) but is the best available quantitative measurement for direct Xa inhibitors [30–32]. However, unlike low-molecular weight heparins, chromogenic antifactor Xa assays may be difficult to clinically interpret as therapeutic ranges for direct Xa inhibitors have not been established for all assays.

Activated charcoal can be considered in recent acute ingestions but, similar to warfarin, may interfere with endoscopy if needed for a gastrointestinal bleed. Activated charcoal decreased the elimination half-life of apixaban from 13.4 h to 5 h when administered at 2 or 6 h post dose [33]. In both activated and nonactivated four-factor PCC and factor VII-corrected coagulation parameters in healthy human subjects who received therapeutic doses of rivaroxaban, but did not reduce blood loss in rabbit models with apixaban or rivaroxaban (there is limited human data for apixaban and edoxaban) [34–41], cryoprecipitate, fresh frozen plasma, or vitamin K are unlikely to have clinical benefit and have not shown to have significant reversal. Despite renal clearance, apixaban and rivaroxaban are highly protein bound and are unlikely to have significant clearance via hemodialysis. Edoxaban is also not amenable to dialysis.

Direct Thrombin Inhibitors

Direct thrombin inhibitors will not significantly change PT and international normalized ratio (INR). Dabigatran will affect activated PTT (aPTT) values, but this will plateau at concentrations ≥ 200 ng/ml, or 1.4–1.8 times normal [42]. Thus, aPTT will have poor correlation with a high degree of anticoagulation but could potentially be used as a qualitative measure. Ecarin clotting time (ECT) and dilute thrombin time (dTT), or hemocot thrombin inhibitor assay, are

the best coagulation parameters to evaluate the anticoagulation effects of dabigatran [42]. ECT is an assay for assessing the effect of direct thrombin inhibition and can be used to concentrations less than 300 ng/ml. Thrombin time (TT) measures the polymerization of fibrinogen to fibrin in the presence of thrombin. Since TT was demonstrated to be too sensitive, dilute TT has been used to quantify the anticoagulation effects of dabigatran. Similar to chromogenic factor Xa assays, ECT and dTT are not readily available at many institutions.

Similar to warfarin and direct Xa inhibitors, activated charcoal can be considered in the setting of an acute ingestion but may have limited clinical utility outside of a recent acute ingestion since it is rapidly absorbed and may interfere with endoscopy in the setting of a gastrointestinal bleed. Activated four-factor PCC and factor VII appeared to achieve the best reversal of coagulation parameters (exogenous thrombin potential and lag time) in humans and have also demonstrated reduced bleeding time, but not blood loss, in animals models [41, 43] (Grade III evidence). No significant change in INR and aPTT was noted after fresh frozen plasma or vitamin K. With characteristics including small molecular size, low protein binding, and significant renal clearance, dabigatran is amendable to conventional hemodialysis and continuous veno-venous hemodiafiltration [44–47]. Case reports of patients with end-stage renal disease on hemodialysis demonstrated clearance of over 60% after 2–4 h [44–46]. Redistribution after hemodialysis has also been described [47]. Despite being amendable to extracorporeal removal, the use of these measures may not be practical. The amount of time to prepare a patient for extracorporeal therapy, in addition to placing a dialysis catheter, can be difficult in a patient with acute life-threatening hemorrhage from dabigatran. Extracorporeal therapy may be considered as an adjunct therapy in a significant bleed, large ingestion, or in the setting of renal failure; however, this should not delay more immediate treatment measures for acute hemorrhage.

Key Points in the Management of Acute NOAC Overdose

1. Chromogenic antifactor Xa assay is the best available quantitative measurement for direct Xa inhibitors.
2. Ecarin clotting time (ECT) or dilute thrombin time (dTT) is the most sensitive coagulation parameter for direct thrombin inhibitors.
3. Gastrointestinal decontamination with activated charcoal may be beneficial.
4. Activated four-factor Prothrombin complex concentrates (50 IU/kg) or activated Factor VII should be used to treat potentially life-threatening bleeding.
5. Idarucimab can be used to treat moderate bleeding from dabigatran.
6. Extracorporeal therapy may be considered as an adjunct therapy in dabigatran toxicity in the setting of significant bleed, large ingestion, or renal failure

Future Antidotes for NOACs

With inconsistent results from readily available pro-hemostatic blood products, specific antidotes are being developed for NOACs and are under clinical trials [48]. Andexanet-alfa is a Fab antibody fragment which is a truncated form of an enzymatically inactive factor Xa and binds and reverses the anticoagulant action of the factor Xa inhibitors. Animal models demonstrate reduced bleeding, and phase I/II studies show correction of laboratory coagulation parameters [49, 50]. Aripazine is another reversal agent originally developed as a reversal agent for heparin and fondaparinux that has shown to have some activity against factor Xa inhibitors and direct thrombin inhibitors. However, it is unclear if it truly reverses the anticoagulant or acts as a procoagulant [41]. Idarucizumab is a recently FDA-approved antibody for reversal of bleeding from dabigatran and is discussed in Anticoagulation Reversal Agents [51, 52].

Anticoagulation Reversal Agents

Vitamin K₁

Vitamin K₁ is an antidote for warfarin toxicity, although it does not reverse enzyme inhibition in the vitamin K cycle (see Fig. 2). Rather, supplemental vitamin K₁ bypasses the inhibited enzymes, allowing for production of active clotting factors. Vitamin K₁ may be administered orally, subcutaneously, or intravenously. The optimal dose and route of vitamin K₁ has not been established [12]. The intravenous route is most predictable but occasionally is associated with anaphylactoid reactions; intravenous vitamin K₁ should be given at a rate not exceeding 5 mg/min, although some have suggested 1 mg/min. [31]

Regardless of route, vitamin K₁ does not have immediate effects, and significant bleeding can be treated with blood products. In massive acute warfarin overdose, three to five daily doses of vitamin K₁ may be necessary, owing to the latter's short plasma half-life [53]. With chronic warfarin toxicity, a single dose often is sufficient.

Common Errors in the Management of Acute Oral Anticoagulant Overdose

Relying on negative urine drug screen to exclude ingestion

Failing to recognize that the coagulopathy may not peak for several days for VKA

Giving only a single dose of vitamin K₁ when some patients require vitamin K₁ doses several times daily

Relying on conventional coagulation measures (PT, INR, PTT) to evaluate the degree of anticoagulation from NOACs.

Coagulation Factors

Patients with life-threatening bleeding require rapid reversal of coagulopathy. Fresh frozen plasma (FFP) generally is administered at a dose of 15 mL/kg. Repeat dosing may be necessary

because coagulation factor half-lives are in the range of several hours. Because many patients receiving warfarin have underlying cardiopulmonary disease, fluid overload is a concern with repeat fresh frozen plasma dosing.

Coagulation factor concentrates also may be used. PCC contains either 3 factors (factors II, IX, and X with dosage based on factor IX content), 4 factors (II, VII, IX, and X), or 4 factors with activated factor VII. Doses of 12 IU/kg have been used in moderate coagulopathy, although 50 IU/kg has been given in the most serious cases, such as intracranial hemorrhage [53] (Grade III recommendation). If only the three-factor concentrate is used, an infusion of factor VII concentrate (25–30 IU/kg) or FFP may be added. Normal coagulation is achieved more rapidly with PCC infusion than with fresh frozen plasma [20, 54, 55] (Grade II-3 evidence). Maintenance therapy with supplemental vitamin K₁ still is necessary when using blood products for VKA because the effects are temporary. Activated factor VII was developed for the treatment of bleeding in hemophilia patients with inhibitors against factors VIII or IX but has been used to achieve hemostasis by activating the extrinsic pathway of the coagulation cascade.

Idarucizumab

Idarucizumab is an intravenous monoclonal antibody fragment available for the reversal of moderate bleeding from dabigatran [51, 52]. Clinical trials (RE-VERSE AD phase III multinational study) show idarucizumab normalized ECC and dTT in 89–98% of patients receiving dabigatran [51, 52] (Grade II-2 evidence). It is recommended to administer a fixed dose of 5 g (in the clinical trial 2.5 g given twice separated by no more than 15 min was used), which is expected to reverse all bound and unbound dabigatran for concentrations up to 99th percentile concentrations of patients enrolled in the Randomized Evaluation of Long-Term Anticoagulation Therapy (Re-LY) trial. It is a 1:1 binding, and the reversal is immediate and sustained for at least 12 h. The half-life of idarucizumab may be prolonged in patients with renal failure.

Drug Interactions with Oral Anticoagulants

Warfarin

As a result of several unfavorable pharmacologic properties of the VKAs, great potential exists for life-threatening interactions with other drugs and foods. First, the VKAs possess a narrow therapeutic index; small changes in drug dosing, metabolism, or distribution can alter coagulability radically. The coumarins are highly bound to serum albumin, and drugs competing for binding to this protein cause an increased free fraction, resulting in enhanced coagulopathy. Coumarin metabolism depends on the activity of several CYP enzymes. Agents that inhibit this metabolism may induce hemorrhage, whereas metabolism inducers may result in loss of effective anticoagulation. The R and S stereoisomers of warfarin are metabolized by different, but overlapping, sets of CYP isoenzymes. The more potent S-warfarin is metabolized primarily by CYP2C9 and to a lesser degree by CYP3A4; R-warfarin is metabolized primarily by CYP1A2 and by CYP3A4 and CYP2C19. Even when the aforementioned issues are tightly controlled, dietary intake of vitamin K can vary, making therapeutic dosing difficult.

Systematic review of reported warfarin-drug interactions found that the drugs listed in Table 3 were considered probable or highly probable to potentiate warfarin. Drugs considered probable or highly probable to reduce warfarin's action are listed in Table 4.

Acetaminophen's apparent potentiation of warfarin's effect has important potential clinical implications. Because of the antiplatelet effects of aspirin and other nonsteroidal anti-inflammatory drugs, physicians often recommend acetaminophen for patients taking warfarin. A few patients taking both of these drugs develop prolonged prothrombin times unaccounted for by warfarin alone. A potential mechanism for this interaction is acetaminophen competitively inhibiting warfarin metabolism or vitamin K carboxylase [1].

Several drugs impair vitamin K metabolism even in the absence of VKAs. Drugs with such a

Rifampin
Sucralfate

warfarin-like effect include cephalosporin antibiotics with *N*-methyl-thiotetrazole side chains (cefamandole, moxalactam, cefoperazone, cefazolin, cefazedone) and salicylates. Aspirin may induce bleeding with an additive effect to that of warfarin and by a synergistic effect through platelet inhibition.

Novel Oral Anticoagulants

A marketed advantage of therapeutic use of NOACs compared with VKAs is fewer drug interactions; however, drug interactions are not completely absent. Rivaroxaban and apixaban are substrates for p-glycoprotein and CYP3A4 [3, 5]. Thus concomitant use of CYP 3A4 inducers or inhibitors can affect plasma concentrations such as HIV protease inhibitors, azole antifungal agents, macrolide antibiotics, rifampin, phenytoin, St. John's wort, and carbamazepine. Dabigatran and edoxaban are also substrates for p-glycoprotein, thus inducers such as rifampin and St John's wort can decrease dabigatran concentrations [4, 6]. P-glycoprotein inhibitors such as amiodarone, cyclosporine, verapamil, and antifungals may increase plasma dabigatran and edoxaban concentrations.

Nonhemorrhagic Complications of VKA

VKAs are associated with several adverse effects unrelated to their therapeutic effect. Nonhemorrhagic complications include warfarin skin necrosis, the "purple toes syndrome," hepatitis, and warfarin embryopathy.

Warfarin Skin Necrosis

Skin necrosis occurs in 1 in 10,000 of patients taking VKAs, with a female:male ratio of 1:4 [56]. Most reported cases have occurred in association with warfarin, although it may occur with any of the coumarin-derived VKAs. The usual presentation is the rapid development of painful,

well-localized hemorrhagic or erythematous skin lesions 3–5 days after initiating VKA therapy (Fig. 4). Occasionally, these lesions are heralded by paresthesias or a pressure-like sensation and poorly demarcated erythema. The lesions become edematous, producing a peau d'orange effect, and may develop petechiae and hemorrhagic bullae. The affected areas develop full-thickness skin necrosis, form eschars, and eventually slough. Small lesions can heal by granulation, but larger lesions usually require surgical débridement, skin grafting, or amputation, depending on their extent.

Warfarin skin necrosis occurs more commonly in obese, middle-aged women, with the preponderance of lesions found on the skin of the breast, buttock, and thigh [56]. Other risk factors include perimenopausal, viral infections, hepatic disease and drug interactions. Patients with protein C or protein S deficiencies and patients receiving large oral loading doses also are at higher risk [55]. These associations suggest that the high-risk population is already prone to thrombosis and that the early hypercoagulable state occurring with oral anticoagulants (due to decreased protein C and S activities) may precipitate localized thrombosis.

Although late treatment clearly consists of wound care and surgical intervention, early treatment before completed skin necrosis is not so obvious. Cessation of warfarin is the mainstay of treatment. If anticoagulation is necessary, substitution of heparin or low-molecular-weight heparins for anticoagulation is recommended [56]. Occasionally, vitamin K is used to reverse the anticoagulation of warfarin. Prostacyclin may be effective (grade III evidence), and patients with protein C deficiency may benefit from infusion of protein C concentrate; however, this can be cost prohibitive [57–59] (Grade III evidence). Even with optimal medical treatment, surgical intervention ultimately is required in about half of patients [56].

Purple Toes Syndrome

The purple toes syndrome is a rare complication of VKA therapy (Fig. 5). Patients can develop

Fig. 4 Coumarin-induced skin necrosis: The patient on the *left* had a deep vein thrombosis, while the patient on the *right* had rheumatic mitral stenosis with atrial fibrillation

(Courtesy of Herbert L. Fred and Hendrick A van Dijk under a Creative Commons license)

purplish discoloration of the plantar surfaces and sides of the toes, usually within 3–8 weeks of initiation of therapy. These lesions are painful and tender, blanch with pressure, and fade with leg elevation. Several cases with biopsy or autopsy specimens show an association with cholesterol microemboli. The purple toes syndrome may represent a sentinel event, presaging further emboli from atherosclerotic lesions, possibly from VKA interference with the healing of ulcerated atheromatous plaques. Other cases of warfarin-related cholesterol embolization (without purple toes) have responded to withdrawal of the offending drug. Consideration should be given to withdrawing VKAs when the purple toes syndrome occurs [60].

Hepatitis

Rare cases of drug-induced hepatitis have been reported with therapeutic dosing of warfarin, phenprocoumon, and acenocoumarol. Hepatocellular injury mimicking a viral hepatitis has been described, occurring within several months of

initiating therapy; less commonly, a cholestatic pattern is evident. In some patients with phenprocoumon-induced hepatitis, the substitution of warfarin has resulted in recurrent hepatitis, suggesting cross-reactivity between these agents. This cross-reactivity is not the rule, because other patients with phenprocoumon-induced hepatitis have been treated successfully with either acenocoumarol or warfarin [61].

Special Populations

Pregnant Patients

Pregnancy generally is considered a contraindication to warfarin therapy owing to teratogenic effects. The US Food and Drug Administration has categorized warfarin as pregnancy class X. Intrauterine exposure has resulted in the fetal warfarin syndrome, characterized by nasal/midface hypoplasia, bone stippling of the epiphyses (evident on plain radiographs), optic atrophy, and mental retardation [62]. Warfarin crosses the placenta, but its mechanism of teratogenesis is

Fig. 5 Purple Toes Syndrome (Image courtesy of Dr. Stephan Moll, University of North Carolina, Chapel Hill, NC, USA)

unclear. Hemorrhage into cartilage with subsequent scarring and calcification has been postulated as causing bone stippling, but this mechanism does not explain adequately the other observed abnormalities [62]. Roughly one sixth of pregnancies with warfarin exposure result in an infant with fetal warfarin syndrome, and another one sixth result in stillbirths or spontaneous abortions; the remaining two thirds result in apparently normal newborns [63]. Heparin usually is substituted for warfarin in pregnant women requiring anticoagulation, although one third of these cases still result in prematurity or stillbirth [18]. Apixaban has no well-controlled studies in pregnant women and classified as pregnancy class B. In animal models, apixaban was not associated with increased risk for fetal malformations but increased risk of bleeding [64]. There are also no well-controlled studies in pregnancy or reported fetal malformations for edoxaban, rivaroxaban, and dabigatran and are all pregnancy class C. There were 10 pregnancies reported in the edoxaban clinical trials (HOKUSAI VTE), outcomes were 6 live births, 3 elective abortions, and

1 spontaneous abortion [65]. Inadvertent rivaroxaban exposure during pregnancy did not lead to increased malformation risk [66]. Although evidence is limited, NOACs are not currently recommended for use in pregnancy [67].

Toxicologic events related to therapeutic administration of thrombolytics, heparins, and antiplatelet drugs are far more common than accidental or intentional overdoses. This chapter focuses on the adverse effects of these agents most commonly encountered by intensivists – in particular, bleeding and heparin-induced thrombocytopenia.

Thrombolytic Therapy

Thrombolytic therapy is indicated in the treatment of acute myocardial infarction, hemodynamically significant pulmonary embolism, hyperacute stroke, and acute peripheral arterial occlusive disease as well as to facilitate the drainage of inflammatory pleurisies. Agents in clinical use include streptokinase (SK), urokinase (UK), alteplase (t-PA), reteplase, and tenecteplase.

Pathophysiology

The hematologic effects of thrombolytic agents may be divided into two phases. In the first phase, drug action results in the cleavage of the arginine₅₆₀-valine₅₆₁ bond of the inactive zymogen plasminogen; this produces a molecule of plasmin, which may be free in the plasma or fibrin-associated. Fibrin-associated plasmin is protected from neutralization by alpha-antiplasmin. In the second phase, plasmin

catalyzed proteolysis of cross-linked fibrin present in clots, the desired therapeutic effect of thrombolytic agents, but also an undesired cause of bleeding complications. Alteplase, reteplase, and tenecteplase display high binding affinity for freshly formed thrombus and, therefore, are relatively selective in activating plasminogen and promoting thrombolysis at the site of clot formation. SK has less specificity and generates both free and fibrinogen-associated plasmin, leading to systemic plasminogen activation. Plasmin catalyzes proteolysis of cross-linked fibrin present in clots. This is the mechanism behind the therapeutic effect of thrombolytic agents and the main cause of bleeding complications.

The duration of plasminogen activation is relatively brief; the half-lives of thrombolytic agents are 6 min for alteplase, 20 min for SK and UK, and 90 min for tenecteplase [1, 2]. In general, circulating plasminogen activator is cleared from the circulation within 6 h of discontinuation, regardless of the thrombolytic agent administered [1, 3, 4].

Plasmin is a nonspecific serine protease. Circulating fibrinogen, factor V, factor VIII, and other coagulation-related proteins besides fibrin are also depleted by plasmin. This is true of all thrombolytics, but particularly SK, because it activates plasminogen systemically. Therefore, after plasminogen activation ceases, a significant anticoagulated state persists due to depletion of multiple coagulation factors. Some have referred to this second phase as the “lytic state,” although this is a misnomer, since lysis of fibrin occurs predominantly in the phase of plasminogen activation [5]. Complete hemostatic recovery from this “second phase” of thrombolytic effect may take 48 h or longer [3, 5–7].

Hypofibrinogenemia is an important characteristic of the second phase. Cleavage of fibrinogen into fibrin is the final common pathway by which clots form, and fibrinogen is essential to platelet aggregation. Fibrinogen concentrations less than 100 mg/dL (≈ 3 $\mu\text{mol/L}$) are common after thrombolytic therapy [3, 6, 8] and are inadequate for normal hemostasis in patients with congenital hypofibrinogenemia and in surgical patients [9, 10]. Intracranial hemorrhage after thrombolytic

therapy has been shown to be related to reduction of plasma fibrinogen by >200 mg/dL (≈ 6 $\mu\text{mol/L}$) [11]. Fibrinogen proteolysis is agent specific and is more severe after administration of SK than after use of t-Pa [4]. Fibrinogen concentrations may take 48 h to normalize after administration of thrombolytics unless it is replaced [6]. Fibrinogen degradation by plasmin results in the accumulation of fragments X, Y, and D which have been shown to exhibit potent anticoagulant effects [12] and to weaken newly formed clot [13]. Factors V and VIII also reach levels that are inadequate for hemostasis in many patients receiving thrombolytic agents. Minimally acceptable levels for factor V and factor VIII (<10 – 30% activity) generally have been based on studies of patients with isolated factor deficiencies [14]. Because thrombolysis involves multiple additional hemostatic defects, it is possible that higher levels are necessary in these patients to control bleeding.

Plasminogen activation also results in platelet dysfunction. Plasmin has been shown to inhibit platelet release of thromboxane B_2 , which recruits other platelets to sites of vascular injury [15]. Plasmin also cleaves platelet glycoprotein Ib [16] and glycoprotein IIb/IIIa [17] – essential for platelet adherence and aggregation. In our experience, inhibition of platelet function commonly is overlooked by physicians treating patients with bleeding complications resulting from thrombolytic therapy.

Clinical Presentation and Life-Threatening Complications

The most common systemic adverse event associated with thrombolytic therapy is hemorrhage, typically associated with vascular access sites or the GI tract [4]. Bleeding in unusual anatomical locations can be particularly life-threatening. Hemothorax and hemomediastinum have been reported in patients receiving thrombolytic agents after undergoing cardiopulmonary resuscitation [18]. Diffuse pulmonary hemorrhage [19] and localized hematoma of the airway [20] can be life-threatening in the absence of exsanguination. But the most immediately life-threatening

hemorrhagic complication of thrombolytic therapy is intracranial hemorrhage (ICH).

The risk for ICH is highest in patients receiving thrombolytics for stroke (6–9%) [21–25], but the risk also is significant in patients with acute myocardial infarction (0.3–0.6%) [26–29] and pulmonary embolism (1.2%) [30, 31]. ICH is typically lobar and usually presents within 24 h of the initiation of thrombolytic therapy. Presenting symptoms, in order of frequency, include decreased level of consciousness, focal neurologic deficits, vomiting, seizure, and headache [32]. Mortality is approximately 50% [33].

Treatment

Bleeding complications of thrombolytic therapy can be minimized by excluding high-risk patients, especially among those with acute stroke. The administration of t-Pa to patients with mass effect or edema on brain computed tomography (CT) has been associated with a 31% rate of ICH, and administration later than 6 h after onset of stroke has been associated with a rate of 53% [34, 35]. Bleeding also may be prevented by avoiding vascular procedures that are unnecessary or in locations that are difficult to compress adequately, such as the subclavian vein.

There are no randomized controlled trials to guide therapy of bleeding complications related to thrombolytics, and suggested treatment, below, represents Level III evidence. Most published data on treatment of pharmacologically associated intracranial hemorrhage relate to oral anticoagulants and cannot be confidently extrapolated to postthrombolytic ICH [2, 36, 37]. Treatment of postlytic bleeding usually includes administration of cryoprecipitate, fresh frozen plasma, and platelets, but these have not clearly been proven to alter the natural course of bleeding [36, 38]. The following serves as a rational (if unproven) approach based on the underlying pathogenesis.

Treatment is initiated with cryoprecipitate and fresh frozen plasma (FFP) administered rapidly to replace clotting factors depleted by plasmin. The standard unit of cryoprecipitate provides a

minimum of 150 mg and an average of 250 mg of fibrinogen. In addition, it contains 80 U of factor VIII. The volume of distribution is equal to the plasma volume – approximately 3200 mL in a 70-kg patient. Intravenous infusion of 10 U of cryoprecipitate increases the fibrinogen concentration by approximately 75 mg/dL (≈ 2.2 $\mu\text{mol/L}$) and the factor VIII level by 30%. Some have suggested that higher doses of cryoprecipitate should be considered in patients with intracranial hemorrhage [36].

FFP contains 180–300 U of factor V per unit. In a 70-kg patient, 6 U of FFP would be required to increase the factor V level by 30%, but smaller doses often result in clinical hemostasis. Laboratory assessment of fibrinogen and factors V and VIII levels can be helpful in guiding therapy if initial transfusions of cryoprecipitate and FFP are unsuccessful. Several factors complicate the interpretation of results, however. If blood is drawn during the phase of plasminogen activation, proteolysis may proceed *in vitro*, falsely diminishing levels of coagulation factors as measured in the laboratory [39].

Platelet transfusion should be considered, especially if the bleeding time is abnormal or dilutional thrombocytopenia occurs as a complication of massive red blood cell transfusion. Theoretically, transfused platelets should function better than native platelets previously exposed to high levels of plasmin. In addition, platelet-bound factor V may help correct factor V deficiency. One unit of single-donor platelets usually provides adequate numbers of functioning platelets. A recent study showed that 0.4 mcg/kg intravenous desmopressin improves platelet function in patients with ICH associated with abnormal platelet function [40]. Although the patients in this study had not received thrombolytic therapy, the theoretical cost/benefit ratio of desmopressin seems acceptable.

Antifibrinolytic agents, aminocaproic acid or tranexamic acid, may be considered early in treatment if transfusion therapy fails to control bleeding. In the case of ICH, they should be considered up front, since their administration is likely to be faster than transfusion therapy, and the prognosis in ICH is likely to be dependent on how quickly bleeding can be controlled

[36, 38]. Aminocaproic acid is a lysine analogue that binds to lysine-binding sites on plasmin and plasminogen. Some have cautioned against the use of aminocaproic acid to control thrombolytic bleeding because of associations with life-threatening thrombotic complications, including stroke, myocardial infarction, limb gangrene, and renal cortical thrombosis [41]. Antifibrinolytic agents would not be expected to be beneficial when the initial phase of plasminogen activation is over (>6 h after infusion of a thrombolytic agent).

Some have suggested that prothrombin concentrate complex (PCC) could be considered in the management of thrombolytic-associated bleeding [36]. However, PCC contains predominantly vitamin-K dependent factors II, VII, IX, and X, and replacing these would be insufficient to re-establish postthrombolytic hemostasis in which fibrinogen, factor V, and factor VIII are depleted. A similar theoretical argument against the likelihood of efficacy would apply to the use of recombinant factor VIIa. Factor VIII inhibitor bypassing activity (FEIBA), otherwise known as activated PCC, might theoretically get around some of this by directly providing thrombin and activated Factor X; however, fibrinogen would still be required for hemostasis to succeed. We were unable to locate published reports of the use of PCC or rFVIIa in patients with postthrombolytic hemorrhage.

Treatment of Clinically Significant Bleeding Due to Thrombolytic Agents

- Cryoprecipitate (approximately 10 U) and
- Fresh frozen plasma (approximately 2–6 U)

If bleeding continues:

- Platelets (1 U single donor or 10 U random donor)

If bleeding continues and thrombolytics were administered within last 6 h:

- Consider aminocaproic acid (Amicar®)

Common Errors in the Diagnosis and Treatment of Complications of Thrombolytic Therapy

- Giving thrombolytics despite late presentations and contraindications
- Failure to recognize platelet dysfunction in patients who are bleeding after thrombolytic therapy

Several nonhemorrhagic adverse effects can occur with thrombolytics. Streptokinase is derived from cultures of group B Streptococci and can induce antibody formation. SK administration has been associated with fever, bronchospasm, anaphylactic reactions, and hypotension [42, 43] – the latter associated with activation of the kallikrein-bradykinin system. Anaphylactic shock, anaphylactoid reactions, and orolingual angioedema have been associated with t-PA [44, 45]. Anaphylaxis and anaphylactoid reactions are treated with fluid resuscitation, epinephrine, H₁ and H₂ receptor antagonists, and corticosteroids.

Unfractionated and Low-Molecular-Weight Heparins and Fondaparinux

Unfractionated heparin (UH) acts by binding to antithrombin and catalyzing the inactivation of thrombin (Factor II), factor Xa, and other clotting factors. Inactivation of thrombin requires a heparin chain length of at least 18 saccharides, and inactivation of factor Xa requires 5 saccharides. Low-molecular-weight heparins (LMWHs) have reduced antithrombin activity compared with UH. The antithrombotic activity of LMWH commonly is attributed to its antifactor Xa activity. The anti-Xa assay is the laboratory test most often used in monitoring and adjusting LMWH [46]. Fondaparinux is a synthetic pentasaccharide derived from the antithrombin binding site of heparin. It has specific anti-Xa, but no anti-IIa activity.

Heparins also have complicated effects on coagulation that are independent of interaction with antithrombin, and their relative importance is uncertain. Heparins (UH and LMWH) trigger

endothelial cell release of tissue factor pathway inhibitor [47–49]. Tissue factor pathway inhibitor is a serine protease inhibitor that blocks tissue factor/factor VIIa-dependent coagulation. Tissue factor pathway inhibitor release seems to account for a significant fraction of heparin's antithrombotic activity [50]. Heparins also interact with heparin cofactor II, which is a serine protease that is structurally similar to antithrombin but has specific antithrombin activity [51]. The antithrombin activity of LMWH might be clinically important, even though low antithrombin/anti-Xa activity previously was thought to be a theoretical advantage of LMWHs [52, 53]. Antithrombin activity can be measured by anti-IIa assays, although these are not typically clinically employed in North America.

Recognition of uncertainty concerning the mechanism of action of LMWH is important during attempts to use anti-Xa activity to guide clinical administration. Because LMWH does not produce isolated factor Xa inhibition, anti-Xa assays do not fully reflect clinical therapeutic or toxic effects [46]. In addition, the anti-Xa test has been reported to exhibit wide interassay variability [54, 55]. Several studies have failed to show a significant relationship between anti-Xa results and the therapeutic or adverse effects of LMWHs [56–58].

Clinical Presentation

Bleeding

The most common toxicological effect of heparin seen in the intensive care unit is bleeding. Rarely, bleeding occurs when single, inappropriately high doses of heparin are given in error. Patients have also received inadvertent heparin boluses when their heparin-loaded dialysis catheters were flushed before first removing the heparin. Pseudoheparin resistance has been reported, in which inappropriately high doses of heparin are erroneously given in order to achieve a “therapeutic” APTT. Elevated factor VIII levels in these patients artificially suppress prolongation of activated partial thromboplastin time (APTT),

leading to unnecessary administration of escalating heparin doses [59].

Most often, hemorrhagic complications occur during appropriate administration of heparin. Although bleeding often is attributed to “overanticoagulation” – defined by supratherapeutic APTT results – several large studies showed no correlation between bleeding and the APTT [60–63]. The most important risk factors for bleeding are patient-specific, such as underlying peptic ulcer disease or thrombocytopenia and procedural trauma.

The gastrointestinal and urinary tracts are the most common sites for heparin-induced bleeding. Approximately 50% of these patients have a discoverable underlying pathologic lesion [64]. Appropriate workup should not be neglected with the logic that the heparin administration alone is a sufficient explanation.

Retroperitoneal hemorrhage often presents with nonspecific findings that commonly are misdiagnosed initially. Patients may complain of back, hip, or thigh pain, and the initial decline in hemoglobin may not be dramatic. Radiation of the pain to the thigh associated with decreased quadriceps strength indicates compression of the femoral nerve [65]. Cullen's or Grey Turner's signs may be noted if sought-for. CT should be considered in any patient receiving heparin who has unexplained back or flank pain.

Rectus sheath hematomas are usually caused by bleeding from the inferior epigastric artery. They present as a painful abdominal mass. Careful examination usually shows the mass to be external to abdominal cavity in the abdominal wall [66]. One case series showed that delays in diagnosis of rectus sheath hematomas are common and seem to contribute to morbidity and mortality [67]. A rectus sheath hematoma may be misdiagnosed as a hernia and “reduced,” with catastrophic results. Rectus sheath hematomas may require embolization or surgical intervention.

Bilateral adrenal hemorrhage may present with nonspecific findings, including abdominal pain, nausea, fever, hypotension, tachycardia, hypoglycemia, and anemia. A cosyntropin stimulation test usually shows inability to produce serum cortisol

levels greater than 18 $\mu\text{g/dL}$ (>497 nmol/L). The hemorrhagic etiology of adrenal insufficiency can be demonstrated by CT [68].

Spinal epidural hematoma presents as severe, persistent back pain radiating in a dermatomal pattern. This condition can occur spontaneously or in association with lumbar puncture or epidural anesthesia. The concomitant use of prophylactic-dose LMWH and indwelling epidural analgesia has been recognized as a risk factor for this complication [69]. Neurologic findings, such as paraparesis, sensory loss, and urinary retention, are indications for urgent decompression.

The nonhemorrhagic toxicologic effects of heparin include hyperkalemia, skin necrosis, and osteoporosis [64]. These effects are not discussed in further detail here.

Treatment

The treatment of clinically severe bleeding related to heparin therapy includes heparin neutralization, supportive care, and transfusion. The effects of UH can be neutralized rapidly by an intravenous bolus of protamine sulfate (Level I evidence). Protamine is a cationic protein which strongly binds to (anionic) heparin. A dose of 1 mg of protamine sulfate neutralizes approximately 100 U of UH; thus, a patient who bleeds immediately after an intravenous bolus of 5000 U of UH requires 50 mg of protamine sulfate. When UH is given as an intravenous infusion, only heparin given during the preceding several hours needs to be included in the dose calculation because the half-life of intravenous UH is approximately 90 min. For instance, a patient receiving a continuous intravenous infusion of 1250 U/h requires approximately 20 mg of protamine sulfate. Neutralization of a subcutaneous dose of UH may require a prolonged infusion of protamine sulfate. The APTT can be used to confirm neutralization of UH [70].

The risk of severe adverse reactions from protamine, such as hypotension and bradycardia, can be minimized by administering protamine slowly (over 1–3 min) [71]. Development of antiprotamine

antibodies and increased risk for allergic reactions, including anaphylaxis, are associated with (1) previous administration of protamine-containing insulin (e.g., neutral protamine Hagedorn [NPH] Insulin), (2) vasectomy, and (3) allergic sensitivity to fish [70, 72, 73]. Patients at risk of protamine allergy can be pretreated effectively with corticosteroids and antihistamines. Recombinant activated factor VII (rFVIIa) has been used successfully to neutralize heparin when protamine reversal is incomplete [74].

Many other methods have been used to neutralize the effects of UH, including heparinase (Neutralase) [75], platelet factor 4 (PF4) [76], extracorporeal heparin removal devices [77], and synthetic protamine variants [78]. These therapies are not widely available.

There is no proven antidote for LMWH. Protamine neutralizes the antithrombin activity of LMWH but fails to completely neutralize anti-Xa activity [79–82]. Protamine-heparin binding is related to the molecular weight of the heparin [83], and it is theorized that failure of anti-Xa neutralization occurs because of reduced protamine binding to low-molecular-weight components [82, 84]. Others have suggested that plasma proteins inhibit protamine binding to LMWH [85].

The clinical significance of incomplete anti-Xa neutralization by protamine is unclear. Animal studies have shown a hemostatic benefit of protamine in microvascular bleeding models, despite persistent anti-Xa activity [86–88]. In a small case series, protamine failed to completely correct abnormal bleeding associated with LMWH in two of three patients [80]. There are no published clinical studies that show a beneficial effect of protamine on bleeding complications of LMWH. However, the package insert for enoxaparin suggests the following approach: if the LMWH heparin was given within 8 h, protamine sulfate may be given in a dose of 1 mg per 100 anti-Xa U of LMWH (1 mg of enoxaparin equals approximately 100 anti-Xa U). A second dose of 0.5 mg of protamine sulfate per 100 anti-Xa U may be administered if bleeding continues. The aforementioned recommendation for protamine's use for LMWH constitutes Level III evidence.

Neither protamine nor FFP transfusion will neutralize the antithrombotic action of fondaparinux. Studies have shown that recombinant activated factor VII (rFVIIa) can reverse laboratory evidence of the antithrombotic effect of fondaparinux, but evidence for clinical efficacy is only at the level of case reports [89–91]. A recent systematic literature review concluded that there is limited evidence to support the use of rFVIIa, (but not PCC or aPCC) in the treatment of life-threatening bleeding associated with pentasaccharide antithrombotic agents [92].

In some cases, surgical repair or endovascular intervention is warranted. Some data suggest surgical intervention is not beneficial in retroperitoneal hemorrhage [67].

Common Error in the Diagnosis and Treatment of Complications of Heparin Therapy

Delay in recognition of occult bleeding, including retroperitoneal hemorrhage, rectus sheath hematomas, and adrenal hemorrhage

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a unique pathologic syndrome characterized by onset of significant thrombocytopenia after the initiation of heparin therapy associated with the presence of thrombogenic antibodies and a high risk (50–80%) of venous and arterial thromboembolism [93–95]. Heparin-associated thrombocytopenia (HAT) and, also previously called, type 1 HIT, are confusing names for a nonpathogenic and nonimmune-mediated decreases in platelet counts that occur in 10–20% of patients in the first 1–2 weeks after heparin is commenced. Platelet counts usually remain $> 100 \times 10^9/L$, and importantly, HAT is not associated with any disease or thrombotic complication and should not be considered a disorder or toxicologic effect of heparin. The main danger these benign, heparin-associated drops in platelet counts produce is when patients experience side effects of drugs given erroneously to treat HIT.

Pathophysiology

The mechanism of HIT is complex and not fully understood, but platelet factor 4 (PF4) plays an important role. PF4 is normally released by activated platelets and neutralizes the antithrombotic effects of endothelial-bound heparans (heparin-like polysaccharides that line human endovascular endothelium) by competing there for binding with antithrombin. PF4 also binds to glycosaminoglycans on the surface of platelets and is chemotactic for neutrophils and monocytes [96]. When exogenous heparin is administered, PF4 dissociates from the endothelium and platelet surface and forms large PF4/heparin complexes [97]. These provoke generation of anti-PF4/heparin antibodies in potentially pathogenic quantities within 4 days after exposure [98–101]. Seventeen percent of patients receiving UH and 8% of patients receiving LMWH develop detectable titers of these antibodies [93, 102], although only 25% of these patients with antibodies develop clinical HIT [103, 104]. In patients who previously received heparin, anti-PF4/heparin antibodies may persist for months, causing immediate-onset HIT if heparin is later re-administered [105].

Anti-PF4/heparin IgG antibodies bind to PF4/heparin complexes on platelet surface and also to IgG-Fc receptors of adjacent platelets [98, 99]. In susceptible individuals, this aggregates and activates the platelets and causes further PF4 release in a pathogenic positive feedback loop [106, 107]. Thrombocytopenia is caused, in part, by platelet consumption as multifocal thrombi subsequently form. This explains a unique clinical aspect of HIT – all other forms of drug-induced autoimmune thrombocytopenia may have an increased risk of *bleeding*, but patients with HIT suffer venous and arterial thromboembolism.

Epidemiology, Clinical Presentation

The incidence of HIT is about ten-times higher in patients receiving UH thromboprophylaxis than in patients receiving LMWH thromboprophylaxis

(3% vs. 0.2%) [108]. But at therapeutic doses, this distinction is lost (1.5% vs. 1.2%) [109]. Even small quantities of UH used to flush intravenous catheters, or incorporated into the linings of intravascular catheters, have been reported to cause HIT [110, 111]. Patients admitted to medicine or surgery are at higher risk than those admitted to obstetrical or pediatric services [112] perhaps due to differences in underlying levels of platelet activation and PF4 release. One large study showed that HIT is very unusual in patients less than 40 year of age [109]. An increased risk for subsequent HIT can be recognized when the patient suffers an acute systemic reaction to heparin administration such as chills, rigors, fever, tachycardia, and dyspnea [113] or dermal plaques or necrosis at heparin injection sites [114]. Very rarely, HIT has been described in relation to fondaparinux administration [115].

Thrombocytopenia typically becomes apparent 5–14 days after the onset of heparin therapy, just as significant levels of anti-PF4/heparin antibodies become detectable. The platelet nadir is usually less than $150 \times 10^9/L$ but almost always higher than $20 \times 10^9/L$, and the median platelet count in one large study was $60 \times 10^9/L$ [95]. Approximately 10% of patients have thromboembolic events consistent with HIT, despite platelet counts greater than $150 \times 10^9/L$ [95]. These patients typically have had 30–50% decreases in platelet counts, albeit to levels greater than $150 \times 10^9/L$. Bleeding complications are unusual, even when thrombocytopenia is severe [116]. Thrombocytopenia can occur within 10 h of heparin initiation in patients who received heparin in the preceding 100 days [105] and can develop weeks to months after exposure to heparin in a rare subset of patients with “delayed-onset HIT.” [117]

Venous thromboembolism occurs in approximately 50% of patients with HIT, with an incidence rate of 5–10% per day [118, 119]. Progressive, recurrent, or bilateral lower extremity deep venous thromboses are seen in 50% of affected individuals, and pulmonary embolism is seen in 25% [116]. It may be difficult to recognize these as distinct signs of HIT in a patient receiving heparin who already has an established diagnosis of venous thromboembolism. Deep venous thromboses often occur at the

site of venous catheters. Rare forms of venous thromboembolism associated with HIT include bilateral adrenal hemorrhage and cerebral dural sinus thrombosis. HIT-associated deep venous thrombosis has progressed to venous limb gangrene in a subset of patients receiving warfarin. The gangrene apparently is triggered by warfarin-induced, acute protein C deficiency [120].

Arterial thrombosis also occurs with increased frequency. Among patients with HIT, aortic, or iliofemoral thrombosis resulting in acute limb ischemia occurs in 5–10%, stroke and myocardial infarction each occur in 3–5%, and spinal cord infarction has been reported [116]. Approximately 35% of patients with HIT who develop thromboembolic complications lose a limb or ultimately die [118, 119].

The clinical suspicion of HIT should be evaluated first by calculating the 4 T score *before* diagnostic tests are ordered, because diagnostic result interpretation is difficult when the pretest probability of disease is very low (unless Bayes’ theorem is explicitly applied). “4Ts” stand for four clinical and laboratory features that are each scored (zero through two points) in relation to how strongly they are predictive for the diagnosis of HIT: Thrombocytopenia, Timing of onset, Thrombosis, and *a*lTernative reasons for thrombocytopenia (see Table 1). The resulting score is well validated and allows stratification of patients with suspected HIT into three categories, representing pretest probability of HIT of approximately 1%, 10% and 50% (see Table 1) [121, 122].

Diagnosis

Previous studies have shown 45–84% of patients referred for laboratory testing are at low risk of HIT based on their 4 T score [123–126]. It could be argued that these patients should not have undergone diagnostic testing in the first place [127], since the prevalence of HIT in this population is likely less than 1% [121–124]. Lower prevalence (or pretest probability) leads to higher false positive rates, even when a diagnostic test with excellent operating characteristics is employed.

Table 1 “Four-Ts” (4Ts) clinical assessment for HIT

Clinical feature	Points assigned for each finding ^a	
	2 points	1 point
Thrombocytopenia	>50% drop with nadir $\geq 20 \times 10^9/L$	30–50% drop or nadir $10\text{--}20 \times 10^9/L$
Timing of platelet count fall	Clear onset in 5–10 days or Onset ≤ 1 day if prior heparin exposure in last 30 days	Unclear onset but consistent with onset in 5–10 days or Onset in ≤ 1 day w/prior heparin exposure 30–100 days previously
Thrombosis or other sequelae of HIT	Confirmed new thrombosis or Skin necrosis at injection site or Acute systemic reaction after IV unfractionated heparin bolus	Suspected new thrombosis or Progressive or recurrent thrombosis or Erythematous non-necrotizing skin lesions at injection sites
Alternative cause	None apparent	Possible but not definite alternative

^aZero points assigned in a category if criteria are not met – for instance, if the patient has a definite alternative cause for thrombocytopenia (e.g., s/p chemotherapy)

Probability of HIT based on 4Ts score:

0–3 points: Low probability of HIT (about 1%)

4–5 points: Intermediate probability (about 10%)

6–8 points: High probability (about 50%)

The diagnosis of HIT is optimally based on clinical criteria above *and* demonstration of heparin-dependent, platelet-activating immunoglobulin G [128]. Highly sensitive and specific washed platelet activation assays for detecting pathologic platelet-activating antibodies include the platelet ^{14}C serotonin-release assay (SRA) in North America and the heparin-induced platelet activation (HIPA) test in Europe. The SRA has been shown to have sensitivity and specificity greater than 98% and 95%, respectively [128]. It is considered sufficiently accurate that a strongly positive SRA result ($>50\%$ serotonin-release) can be used as a proxy for the clinico-pathological diagnosis of HIT in most clinical situations [93, 129]. However, the SRA is technically demanding

and available only at specialized testing centers. Consequently, many centers depend on commercial enzyme-linked immunosorbent assays designed to detect antibodies directed against platelet factor 4/heparin (anti-PF4/H ELISA) [130].

A positive ELISA test in a patient with intermediate or high probability of HIT by 4 T score is typically sufficient to make the diagnosis of HIT. But ELISA results can be difficult to interpret. The manufacturer of the ELISA test most commonly used in the USA (Gen-Probe GTI Diagnostics, Waukesha, WI, USA) defines a positive result as >0.4 optical density (OD) units based on analysis of anti-PF4/heparin antibody levels in populations of healthy volunteers not receiving heparin [131]. However, the presence of anti-PF4/heparin antibodies at this low threshold has poor specificity when used to diagnose HIT in patients receiving heparin [124, 132–134]. Although the sensitivity of the anti-PF4/H ELISA is as high as 99%, the specificity is reported to be 50% or less in clinical studies [123, 133] that use the manufacturer-recommended cutoff. One reason for the low specificity of the anti-PF4/H ELISA is that (unlike the SRA) only a minority of antibodies detected by ELISA have the pathogenic characteristics necessary to activate platelets and thus to trigger HIT [123]. Indeed, although 25–30% of patients referred for suspicion of HIT have elevated anti-PF4/H antibody levels by ELISA (>0.4 OD units), as few as 1–7% overall satisfy the full clinic-pathological diagnostic features of HIT [123, 124, 133]. The low specificity of the currently accepted cutoff for a positive anti-PF4/heparin ELISA tends to lead to clinical overdiagnosis of HIT [127].

Our published analysis suggests that a Bayesian approach to diagnosis of HIT, incorporating the 4 T score and stratified interpretation of the ELISA result as depicted in Table 2 below, is most likely to yield accurate decisions [132]. We have recently validated this approach at our center, although good bedside judgment might trump an algorithmic approach in some cases.

In summary, diagnostic tests should generally not be ordered unless the clinical picture is consistent with HIT (at least intermediate probability

Table 2 Optimized algorithm for interpreting anti-PF4/H ELISA results in patients suspected of having HIT

Pretest probability of HIT by 4 T score	ELISA result (OD)	Post-test probability of HIT (%) Based on		Reasonable clinical action
		IgG ELISA	Poly-spec. ELISA	
Low (0–3 points) <i><1% chance patient has HIT</i>	>2.00	51%	42%	Order SRA ^a
	1.50–1.99	11	7	
	0.60–1.49	1	1	HIT ruled out ^b
	<0.6	0	0	
Intermediate (4–5 points) <i>~10% chance patient has HIT</i>	>2.00	92	91	Treat HIT
	1.50–1.99	56	44	Order SRA ^a
	0.60–1.49	14	11	
	<0.6	0	0	HIT ruled out ^b
High (6–8 points) <i>~50% chance patient has HIT</i>	>2.00	99	99	Treat HIT
	1.50–1.99	92	87	
	0.60–1.49	59	54	Order SRA ^a
	<0.60	2	0	

^aMost patients undergoing SRA testing should be treated for HIT pending the result

^bAssumes that the pretest probability for HIT has not been altered substantially by subsequent clinical and/or laboratory finding

by 4 T score). A negative ELISA is good at ruling HIT out, but values of 0.4–0.8 OD, which are considered “positive” by the manufacturer, are actually diagnostically equivocal. When there is uncertainty about the diagnosis, an SRA is the gold standard.

Treatment

When HIT is reasonably suspected (4 T score indicating at least an intermediate risk of HIT), all heparin should be discontinued immediately pending confirmatory laboratory testing. Care should be taken to be sure that heparin flushes and heparin-coated intravenous catheters are not overlooked. Alternative antithrombotic therapy should be started immediately in patients with suspected HIT with thromboembolism, and in patients with laboratory-confirmed HIT, even in the absence of overt thromboembolic complications. LMWH consistently cross-reacts with existing heparin/platelet factor 4 antibodies and cannot be used in therapy of HIT due to UH [135].

Argatroban is a synthetic direct thrombin inhibitor and the only FDA-approved treatment

for the treatment of HIT in the general patient population. Two historically controlled trials showed a reduction in new thromboembolic events, limb amputation, and death in patients with HIT treated with argatroban, representing Level II evidence effectiveness [136, 137]. The initial infusion dose is 2 µg/kg/min, adjusted to attain an APTT value 1.5–3 times baseline, with a maximum of 100s. Dose reduction is recommended in patients with heart failure, and the drug should not be used in patients with significant liver dysfunction.

Platelet counts usually begin to improve within 48 h of heparin discontinuation and typically resolve within 2 weeks; however, thrombotic risk remains elevated for approximately 6 weeks due to persistence of circulating anti-PF4/heparin antibodies [94], requiring prolonged therapy even after platelet counts have completely recovered and even when no overt thromboembolic complications are recognized [138]. Therefore, after the platelet count has recovered (e.g., $>150 \times 10^9/L$), warfarin should be started and overlapped with argatroban for approximately 5 days [138]. Argatroban prolongs the prothrombin time, so during the overlap period, an INR greater than 4 usually is typically required to account for the additive actions of

argatroban and warfarin. The recommended duration of warfarin therapy for HIT is 4 weeks in the absence and 3–6 months in the presence of clinically recognized thromboembolism [138].

Bivalirudin and fondaparinux are possible alternatives to argatroban. Fondaparinux has several advantages – it is given as a single daily subcutaneous dose (7.5 mg for patients who weigh 50–100 kg and 10 mg for patients >100 kg), does not require monitoring, and is relatively inexpensive. Although fondaparinux belongs to the heparin family of antithrombotic agents, it does not appear to incite or crossreact with anti-PF4/heparin antibodies associated with HIT [139]. Its efficacy is supported by several small case series [140–143], but it is not FDA-approved for the treatment of HIT (Level III evidence). Fondaparinux is contraindicated in patients with creatinine clearance < 30 mL/min. Plasmapheresis has been rarely utilized in HIT in an attempt to reduce anti-PF4/H antibodies [144].

Common Errors in the Diagnosis and Treatment of Heparin-Induced Thrombocytopenia

- Failure to monitor for or consider the diagnosis
- Failure to stop all heparin immediately while the diagnosis is being confirmed
- Failure to recognize that the cross-reactivity between heparin and low-molecular-weight heparin is 100% in patients with heparin-induced thrombocytopenia

Antiplatelet Drugs

P2Y₁₂ Platelet Receptor Blockers

Ticlopidine, clopidogrel, prasugrel, and ticagrelor are antiplatelet agents that act by antagonizing P2Y₁₂ receptors on the surface of platelets. P2Y₁₂ is a G-coupled transmembrane receptor that activates platelets by decreasing intracellular cAMP. P2Y₁₂ receptor antagonists are indicated for secondary prevention of stroke, for elective percutaneous coronary intervention, and in acute myocardial infarction. Ticlopidine, clopidogrel,

and prasugrel are converted to active metabolites that covalently and irreversibly bind to P2Y₁₂ receptors, explaining inhibition of ADP-mediated platelet aggregation for the life of the platelet. Ticagrelor has no such metabolite and reversibly binds to P2Y₁₂ receptors, explaining a somewhat shorter duration of action after termination of therapy. Overall, patients who present with bleeding who have received a P2Y₁₂ receptor antagonist within approximately 10 days should be considered to have potentially significant platelet dysfunction. We have seen several episodes of life-threatening bleeding associated with these agents in patients who had undergone high-risk procedures, such as gynecologic-oncologic surgery, without withholding a P2Y₁₂ receptor antagonist for an adequate period of time for platelet function to recover.

If the bleeding is serious, platelet transfusion is warranted, even if the platelet count is normal. However, there are no controlled trials that have demonstrated changes in survival or decreased bleeding in patients taking these drugs, making the recommendation for platelet transfusion based on Level III evidence and in vitro studies on platelet function. In vitro studies demonstrate that ticagrelor's reversible binding to platelets allows it to inhibit donor platelet function, as well. Thus, as long as ticagrelor is still circulating, platelet transfusion would not be expected to be as effective in comparison with patients receiving ticlopidine, clopidogrel, or prasugrel. Effective reversal agents for P2Y₁₂ receptor antagonists are not currently available or well studied. Desmopressin has been shown to repair platelet aggregation inhibited by clopidogrel, in an animal model [145], but not repair platelet aggregation in the blood of subjects receiving ticagrelor [146]. rFVIIa has been shown to restore platelet aggregation and thrombin generation in ex vivo blood treated with prasugrel [147], and in blood from patients receiving aspirin/clopidogrel [147].

Thrombotic thrombocytopenic purpura (TTP) is one of the hematologic complications of this class of drugs that might present in the ICU. TTP is a life-threatening syndrome characterized by microangiopathic hemolytic anemia and thrombocytopenia sometimes in association with renal

insufficiency, fever, and central nervous system abnormalities. Laboratory findings consistent with the diagnosis of TTP include elevated lactate dehydrogenase; schistocytes on blood smear; and normal prothrombin time, partial thromboplastin time, and fibrin degradation products. No cases of ticlopidine-associated TTP were reported during phase III trials [148], but postmarketing surveillance has shown that TTP occurs in approximately 1/1600–1/5000 patients receiving ticlopidine. Mortality of TTP is 20–60% [148–150].

Ticlopidine seems to induce the formation of autoantibodies to von Willebrand factor metalloproteinase in patients who subsequently develop TTP; these antibodies reduce degradation of ultralarge von Willebrand factor multimers, increase binding of platelets to von Willebrand factor, and cause widespread microvascular thromboses [151]. Most patients with ticlopidine-associated TTP develop it within 3 months of initiating therapy [148], but a significant minority may develop delayed TTP. A nonrandomized study showed a reduction in mortality from 60% to 20% in patients with ticlopidine-associated TTP receiving plasma exchange [148]. Ticlopidine also has been associated with life-threatening neutropenia and aplastic anemia.

Clopidogrel is closely related chemically to ticlopidine and has largely replaced it in clinical use. TTP has been reported in association with its use, however [152]. Clopidogrel-associated TTP has occurred within the first 2 weeks of therapy and seems to respond to plasma exchange.

Glycoprotein IIb/IIIa Receptor Antagonists

The glycoprotein IIb/IIIa receptor plays a pivotal role in platelet aggregation. When activated by adhesion or agonist receptors, this integrin can bind soluble ligands, such as fibrinogen and von Willebrand factor that mediate platelet cohesion. A detailed review of this process is referenced [153]. Platelet aggregation is particularly important in the formation of arterial clots. Antagonists of the glycoprotein IIb/IIIa integrin

have been found to be efficacious in the therapy of acute coronary syndromes. The intravenous agents abciximab, eptifibatide, and tirofiban hydrochloride are in clinical use in the USA for patients with coronary artery disease.

The pharmacokinetic properties of these agents are important in the management of hematologic complications. Abciximab has the highest affinity for platelet binding and the slowest rate of dissociation. Although the plasma half-life is 26 min, the “biologic” half-life (recovery of platelet aggregation) is approximately 8 h. Platelet-associated abciximab can be detected for more than 14-day postinfusion [154]. Eptifibatide and tirofiban have lower platelet binding affinity and significantly faster dissociation kinetics. Their serum half-lives are approximately 2 h, and their biologic half-lives are less than 4 h [154]. After a dose of any of these agents, the bleeding time corrects more rapidly than does platelet aggregation [155] and is of little utility in the evaluation of bleeding complications [156]. It is possible that thromboelastography might be an option in this regard [157], but this is not clinically well studied.

Bleeding associated with glycoprotein IIb/IIIa antagonists occurs most commonly at the site of intravascular catheters in the groin. Although this bleeding is overt, the quantity of blood loss often is underestimated, particularly when bleeding from the femoral artery tracks up into the retroperitoneal space. We have seen several patients experience life-threatening hemodynamic compromise from groin hemorrhages that were rapidly clinically recognized but treated inadequately. Abciximab given within 12 h of emergent cardiac surgery has been associated with a significant increase in perioperative bleeding [158]. The risk of intracranial hemorrhage with glycoprotein IIb/IIIa antagonists is 0.07% – equal to the risk with heparin [159]. Diffuse alveolar hemorrhage has been reported by several authors [160, 161].

Manual compression of enlarging groin hematomas is often sufficient treatment, but in some cases consultation of interventional radiology or vascular surgery might be indicated, particularly when femoral artery pseudoaneurysm is present. Methods to repair hemostasis are agent specific.

The unbound fractions of eptifibatide and tirofiban typically are large enough to negate any benefit of platelet transfusion. Both of these agents undergo rapid renal clearance, with significant recovery of platelet function within 4 h [162]. Treatment of bleeding associated with these agents is often supportive. It is unclear whether either agent is dialyzable. In contrast, abciximab is almost entirely platelet bound in vivo, with little unbound drug to inhibit the function of transfused platelets. In addition, the antiplatelet effects of abciximab can last up to 48 h, making it much more likely that platelet transfusion might be beneficial [162].

Glycoprotein IIb/IIIa receptor antagonists are associated with severe thrombocytopenia that can occur within the first day of initial administration [163–166]. Thrombocytopenia in this situation is associated with severe bleeding complications, myocardial infarction, and death [164, 167, 168]. It has been hypothesized that binding of glycoprotein IIb/IIIa receptor by these drugs might expose a “ligand-induced” neoepitope on the platelet surface, similar to epitopes associated with platelet senescence and to which some patients already have preexisting antibodies [169].

The first step in evaluating thrombocytopenia due to glycoprotein IIb/IIIa receptor antagonist is to rule out pseudothrombocytopenia by repeating the platelet count in a tube anticoagulated with sodium citrate rather than EDTA. If pseudothrombocytopenia is ruled out, glycoprotein IIb/IIIa inhibitors be discontinued when the platelet count decreases to less than $100 \times 10^9/L$ [169]. HIT should be considered in the differential diagnosis, but is usually clinically distinguishable because it typically does not occur as rapidly or cause as severe thrombocytopenia ($<30 \times 10^9/L$) as is commonly associated with glycoprotein IIb/IIIa inhibitors. Platelet transfusion should be considered if the patient is bleeding, the platelet count decreases to less than $20 \times 10^9/L$, or an emergency invasive procedure is needed [169]. Platelet count recovery typically occurs within 5 days after discontinuation of eptifibatide and tirofiban and within 2 weeks after abciximab [170, 171].

Antidiabetic agents include insulin and nine classes of oral drugs:

1. Sulfonylureas
2. Meglitinides
3. Biguanides
4. Glitazones
5. α -glucosidase inhibitors
6. Glucagon-like peptide-1 (GLP-1) agonists
7. Dipeptidyl-peptidase-4 (DPP-4) inhibitors
8. Amylin analogs
9. Sodium-glucose cotransporter 2 inhibitors (SGLT2 inhibitors)

Although they may have other effects, antidiabetic agents are used primarily for the treatment of hyperglycemia, the cardinal feature of all forms of diabetes mellitus and the consequence of overproduction and underuse of glucose due to underlying insulin deficiency (low levels of circulating insulin) and insulin resistance (decreased tissue responsiveness to insulin). Insulin therapy provides exogenous hormone, sulfonylureas and meglitinides enhance endogenous insulin secretion, biguanides and glitazones enhance the tissue insulin activity, α -glucosidase inhibitors reduce the intestinal absorption of carbohydrates. More recent antidiabetic agents, GLP-1 agonists, DPP-4 inhibitors, and amylin analogs, affect glycemic control primarily by slowing gastric emptying, decreasing postprandial glucagon production, and overall decreasing food intake. SGLT2 inhibitors, however, are a new class which blocks reabsorption of glucose in the kidneys, thereby increasing glucose excretion in the urine. Insulin, sulfonylureas, and meglitinides can cause hypoglycemia and are classified as hypoglycemic agents. Biguanides, glitazones, α -glucosidase inhibitors, GLP-1 agonists, DPP-4 inhibitors, amylin analogs, and SGLT2 inhibitors do not on their own cause hypoglycemia and are characterized as antihyperglycemic agents. However, they can potentiate the action of hypoglycemic agents and precipitate hypoglycemia when added to a therapeutic regimen that includes hypoglycemic agents. Biguanide exposure also has been associated with the development of lactic acidosis.

Chemistry and Pharmacokinetics

Insulin

Insulin is a protein hormone that is related structurally to the somatomedins or insulin-like growth factors, which act as paracrine modulators [1, 2]. It consists of two chains of amino acids linked by disulfide bonds and is synthesized by β cells of pancreatic islets of Langerhans. These cells first produce a single long chain of amino acid known as *preproinsulin*. After entering the rough endoplasmic reticulum, an end portion of preproinsulin is cleaved off to form proinsulin (Fig. 1). Proinsulin then spontaneously folds on itself as disulfide bonds are established between the two ends. It subsequently is packaged in vesicles and transported to the Golgi complex. Here, proinsulin is repackaged in secretory granules along with enzymes that convert it to a double-stranded insulin molecule by cleaving a connecting segment or C peptide from the fold or midportion of proinsulin. Insulin stored in granules complexes with zinc to produce insulin hexamers, a concentrated crystalline form of insulin. This process facilitates the conversion of proinsulin to insulin. Although C peptide has no known biologic activity, equimolar amounts of insulin and C peptide are produced from the cleavage of proinsulin and released into the circulation from secretory granules (along with small quantities of proinsulin).

Insulin for therapeutic use originally was obtained by extracting it from pork or beef pancreas, with doses and concentrations expressed in units of insulin based on bioassay in rabbits. In 1921, Banting and Best were the first to use such an extract to treat a human patient successfully. Pork and beef insulins, which differ from human insulin by one (pork) and three (beef) amino acids, and mixtures of these insulins are still available. Human insulin, now more widely used, is prepared by enzymatic modification of pork insulin or produced by strains of *Escherichia coli* or *Saccharomyces cerevisiae* using recombinant DNA technology. Insulin lispro is a recombinant DNA-derived human insulin analogue. Insulin doses still are expressed in bioassay units, but

Fig. 1 Amino acid sequence of human proinsulin. When the connecting peptide is removed (the portion between the arrows), the remaining primary structure is that of insulin. Amino acid substitutions in the sequence for pork insulin and beef insulin also are noted (From Lawrence JC: Insulin

and oral hypoglycemic agents. In Brody TM, Larner J, Minneman KP [eds]: *Human Pharmacology: Molecular to Clinical*, 3rd ed. St. Louis, Mosby, 1998, p 549, with permission)

solutions and suspensions now have been standardized to concentrations of 100 U/mL. This standardization is also true for fixed combinations, such as those containing 70/30 U/mL and 50/50 U/mL of regular and NPH (isophane) insulin (e.g., Humulin, Novolin). As with endogenously stored insulin, exogenous preparations often consist of hexameric insulin complexed with zinc.

Insulin must be given parenterally, usually by subcutaneous injection, although an inhaled form of insulin (Afrezza) was approved by the US Food and Drug Administration in 2014 [1–4] (US brand names are given as examples. These may be similar or different in other countries.). Therapeutic subcutaneous doses range from 0.2 to 2.5 U/kg/day. After absorption (or secretion), hexameric insulin dissociates and circulates in the blood as the more biologically active free

monomer. It is distributed in extracellular fluid, has a volume of distribution of about 0.4 L/kg, and is minimally bound to plasma proteins. Elimination occurs by liver, kidney, and muscle metabolism, with a half-life of 5–9 min after intravenous injection. The half-life is prolonged in patients with antiinsulin antibodies, patients with renal failure, and, to a lesser extent, patients with hepatic disease. The duration of effect of insulin after subcutaneous administration is much longer (hours to days). More importantly, it depends on the insulin formulation. Differences in the duration of action after subcutaneous administration reflect differences in the rate of dissolution and absorption (not metabolism) of insulin preparations, and these differences affect times of onset and peak effect and apparent half-life. Regular insulin is the only preparation that can be given

intravenously. By this route, its action begins in minutes, peaks within 0.5 h, and lasts 2–3 h.

Under fasting conditions, the pancreas secretes about 1 U (40 µg [7 nmol]) of insulin per hour in nondiabetics, resulting in an average serum insulin level of about 12 µU/mL (0.5 ng/mL [84 pmol/L]) by radioimmunoassay. After ingestion of a meal, insulin levels in nondiabetics average about twice this amount. Normally, about 10% of the immunoreactive insulin level is due to the presence of proinsulin, with normal levels of the latter being 36–126 ng/mL (4–14 pmol/L). Because proinsulin has a longer half-life than insulin (about 17 min), a slightly higher fraction is seen in non-insulin dependent diabetes. A much higher fraction of proinsulin (20–80%) is seen in patients with insulinomas because of abnormal processing of this peptide by these tumors. Also, because proinsulin has only about $1/50$ the biologic activity of insulin, the effective insulin level is actually lower than that determined by radioimmunoassay. Similarly, because C peptide has a longer half-life than insulin (about 30 min), serum concentrations of this protein (also measured by radioimmunoassay) are higher than serum concentrations of insulin (1–4 ng/mL [500–2000 pmol/L]). Lower insulin and C peptide concentrations may be seen in untreated insulin-dependent diabetics who are insulin deficient, and higher concentrations may be seen in non-insulin dependent diabetics (treated and untreated) who are insulin resistant. Serum insulin concentrations may be many times higher in insulin-dependent diabetics treated with nonhuman insulin because they rapidly develop antibodies capable of binding large amounts of exogenous insulin in the plasma, and radioimmunoassays measure total rather than free immunoreactive insulin (unless a preliminary separation step is employed) (Table 1).

Sulfonylureas

The sulfonylureas (substituted arylsulfonylureas) are related structurally to sulfonamide antibiotics (Fig. 2) [1–3]. Agents in current use differ in potency with the newer or second-generation

Table 1 Classification and pharmacodynamics of insulin preparations^a

Classification/ preparation	Onset (h)	Peak (h)	Duration of action (h)
Rapid acting			
Lispro	0.25–0.5	0.5–2.5	3–6
Regular (crystalline)	0.3–1	1–5	5–10
Intermediate acting			
Lente	1–3	6–14	16–24
NPH (isophane)	1–2	6–14	16–24
Long acting			
Ultralente	4–6	8–20	24–36

^aAfter subcutaneous administration

analogues, being about 100 times more potent than the first-generation agents. They also differ in half-life and duration of action but are similar in terms of their high (>90%) plasma protein binding, primarily to albumin, and low (0.1–0.2 L/kg) volumes of distribution. Atypically, and for unclear reasons, their duration of action does not correlate with half-life [5].

Sulfonylureas are well absorbed from the gastrointestinal tract with bioavailabilities of 80% or greater. Food can decrease their absorption and bioavailability. Antihyperglycemic effects typically begin within 1 h and peak in 2–6 h, with first-generation agents having a longer time to peak effect than second-generation agents. The coadministration of other drugs that are highly protein bound (e.g., oral anticoagulants, phenytoin, salicylates and nonsteroidal antiinflammatory agents, sulfonamides) can displace sulfonylureas from binding sites and enhance their effects (and vice versa). These agents are eliminated by hepatic metabolism (to a variety of active and inactive metabolites) and renal excretion (along with their metabolites). Hepatic or renal insufficiency can prolong their half-lives. The renal elimination of chlorpropamide is increased in alkaline urine and decreased in acidic urine. Because all sulfonylureas are weak acids with pK_a values of about 5, the urinary excretion of other agents also is likely to be dependent on urinary pH. Chlorpropamide, which has relatively

Fig. 2 Chemical structures of sulfonylurea hypoglycemic agents

greater renal elimination, and acetohexamide, glyburide, and tolazamide, which have active metabolites, are more likely than other agents to cause hypoglycemia in patients with renal failure (Table 2).

Meglitinides

Meglitinides are analogues of the nonsulfonylurea moiety of glyburide [6, 7]. Repaglinide (Prandin) and nateglinide (Starlix) are the only agents in this

Table 2 Selected pharmacokinetics and pharmacodynamics of sulfonylureas

	Usual dose (mg/day)	Half-life (h)	Duration of action (h)
First-generation agents			
acetohexamide (Dymelor)	500–750 ^a	1.4 (0.8–2.4)	12–24
Chlorpropamide (Diabinese)	250–500 ^b	36 (25–60)	24–72
Tolazamide (Tolinase)	100–1000 ^a	7 (5–11)	10–24
Tolbutamide (Orinase)	1000–2000 ^a	7 (4–25)	6–24
Second-generation agents			
Glimepiride (Amaryl)	1–4 ^b	5 (2–8)	24+
Glipizide (Glucotrol)	10–20 ^a	2.8 (1.1–3.7)	12–24
Glyburide ^c (DiaBeta, Glynase, Micronase)	3–20 ^b	1.6 (0.7–3)	24
Gliclazide (Diamicon)	40–240 ^b	12–20	24

^aOnce a day or divided^bOnce a day^cAlso known as glibenclamide

class currently available in the USA. The recommended dose is 0.5–4 mg for repaglinide and 60–120 mg for nateglinide two to four times a day before or with meals. These agents are well absorbed orally and are highly (>98%) bound to plasma proteins, primarily albumin. They have relatively low volumes of distribution (about 0.4 L/kg) and are eliminated by hepatic metabolism, with renal excretion of inactive metabolites. Half-lives are about 1.5 h. Their elimination may be impaired in patients with hepatic or renal insufficiency. Because cytochrome P-450 enzymes, CYP3A4 in particular, are partly responsible for their metabolism, the coadministration of drugs that induce CYP3A4 (e.g., barbiturates, carbamazepine, rifampin, pioglitazone) or inhibit CYP3A4 (e.g., azole antifungals, calcium channel blockers, cimetidine, human immunodeficiency virus protease inhibitors, macrolide antibiotics, oral contraceptives) could potentially decrease or increase the effect of meglitinides, respectively.

Biguanides

Biguanides (diguanydes) are derivatives of guanidine [1–3, 8]. Above-ground parts of the flowering plant *Galega officinalis* (Goat's rue, French lilac, Italian fitch) contain the guanidine analogues galegine and 4-hydroxygalegine. This plant was used in medieval Europe for the treatment of diabetes and is still available as an herbal

medicine, primarily used as a diuretic and secondarily as supportive therapy in diabetes. Metformin (Glucophage) is the only biguanide prescription medication currently available in the USA. It has been in clinical use in Europe since 1970 but was withdrawn from most markets in 1977 along with the related agent phenformin because use of the latter was associated with a low but unacceptable incidence of fatal lactic acidosis. Although this complication also can occur during metformin therapy, it is extremely rare and much less common than it is with phenformin. Metformin was reintroduced in Europe in the late 1980s and approved for use in the USA in 1995.

Metformin is absorbed slowly and incompletely from the gastrointestinal tract. It does not bind to plasma proteins and has a volume of distribution of 3.7 L/kg. It is eliminated by urinary excretion and to a lesser extent in the feces as unchanged drug. The usual therapeutic dose is 500 or 850 mg, taken during or after meals; doses generally should not exceed 2550 mg/day. Sustained-release formulations (e.g., Glucophage XR) are also available for once- or twice-daily dosing (e.g., 2000 mg once a day or 1000 mg twice a day). Bioavailability is about 50%. Antihyperglycemic effects begin about 1 h after ingestion and persist for 12 h (longer with sustained-release formulations). The half-life averages 4–8 h and is prolonged in patients with renal impairment. Renal insufficiency decreases the volume of distribution and increases peak

plasma drug levels and the risk of toxicity. For these reasons, metformin is contraindicated in patients with renal disease or dysfunction and in patients who have conditions that predispose to renal impairment, such as congestive heart failure, dehydration, sepsis, and shock. It also is recommended that therapy be discontinued when performing radiographic imaging with intravenous iodinated contrast material, which can cause renal failure (particularly in diabetics), and not be resumed until postprocedure renal function is determined to be normal. Because metformin undergoes proximal tubular secretion and glomerular filtration, its renal clearance is about 3.5 times that of creatinine. Cimetidine and possibly other drugs that undergo renal tubular secretion, such as amiloride, digoxin, morphine, quinidine, procainamide, triamterene, trimethoprim, and vancomycin, can compete with metformin for proximal tubular transport and increase its plasma level.

Thiazolidinediones

Thiazolidinediones (glitazones) currently available in many countries are pioglitazone (Actos) and rosiglitazone (Avandia) [3]. Lobeglitazone has very limited availability worldwide. Troglitazone (Rezulin), the first widely used thiazolidinedione, was introduced in the USA in 1997 but removed from the market in March 2000 because of potentially fatal idiosyncratic liver toxicity associated with its use. The risk of this toxicity seems to be much less with pioglitazone and rosiglitazone.

Therapeutic doses are 15–45 mg/day for pioglitazone and 2–8 mg/day for rosiglitazone. Both drugs are well absorbed from the gastrointestinal tract, are highly (>99%) bound to plasma proteins (primarily albumin), have relatively small volumes of distribution (0.3–0.6 L/kg), and are eliminated by hepatic metabolism. Half-lives are approximately 3 h, and there is renal excretion of active and inactive metabolites. Pioglitazone, but not rosiglitazone, is metabolized by CYP3A4 and could be subject to interactions with drugs that are metabolized by or inhibit this enzyme (see under section “[Meglitinides](#)”).

α -Glucosidase Inhibitors

α -Glucosidase inhibitors currently available in the USA include acarbose (Precose) and miglitol (Glyset) [3]. Therapeutic doses of acarbose and miglitol are 25–100 mg three times a day given with meals. Acarbose, an oligosaccharide, has limited systemic absorption and is eliminated by metabolism within the gut, primarily by intestinal bacteria but also by digestive enzymes. Miglitol, a monosaccharide derivative, is well absorbed after oral administration. It has negligible protein binding, has a small volume of distribution (0.18 L/kg), and is eliminated by renal excretion of unchanged drug. Although its elimination may be impaired in patients with renal insufficiency, absorption does not contribute to its therapeutic effect (see later), and dosage adjustments are unnecessary in these patients.

Glucagon-Like Peptide-1 Agonists

Available glucagon-like peptide-1 (GLP-1) agonists in the USA include exenatide (Byetta), liraglutide (Victoza), albiglutide (Tanzeum), and dulaglutide (Trulicity). These medications are only available as subcutaneous injections. Exenatide is a synthetic formulation of exendin-4, which is found in Gila monster (*Heloderma suspectum*) saliva. This naturally occurring substance shares 53% of its sequence with GLP-1 [9]. However, unlike GLP-1, these agonists are resistant to degradation by dipeptidyl peptidase 4 (DPP-4), making them useful clinically. Exenatide should not be used in patients with severe renal impairment (creatinine clearance <30 mL/min). Liraglutide, albiglutide, and dulaglutide are long-acting GLP-1 agonists, where liraglutide is dosed once daily and others are dosed once weekly. These also have structural modifications to prevent degradation by DPP-4 and to prolong half-lives. There is little experience with using these medications in patients with severe renal impairment. Cases of acute pancreatitis have been reported in patients on GLP-1 agonists. The evidence at this time is inconclusive, but these medications should be used with

Table 3 Dosing and half-lives of GLP-1 agonists

	Usual dose	Half-life (h)
Exenatide IR ^a	5–10 mcg	2.4
Exenatide ER ^b	2 mg	336
Liraglutide ^c	0.6–1.8 mg	13
Albiglutide ^b	30–50 mg	120
Dulaglutide ^b	0.75–1.5 mg	120

^aTwice daily

^bOnce weekly

^cOnce daily

caution in patients who have a history of pancreatitis and should be discontinued if patients should develop acute pancreatitis during use [10] (Table 3).

Dipeptidyl Peptidase-4 Inhibitors

The dipeptidyl peptidase-4 (DPP-4) inhibitors available in the USA include sitagliptin (Januvia), saxagliptin (Onglyza), linagliptin (Tradjenta), and alogliptin (Nesina). Vildagliptin, trelagliptin, and anagliptin are approved in some other countries. The DPP-4 inhibitors are taken orally and are generally readily absorbed. Therapeutic doses are 100 mg/day for sitagliptin, 2.5–5 mg/day for saxagliptin, 5 mg/day for linagliptin, and 25 mg/day for alogliptin. Peak plasma concentrations are within 1–3 h. With the exception of linagliptin, which is 70–80% protein bound, protein binding is generally low. The volumes of distribution for the DPP-4 inhibitors are modest for sitagliptin, saxagliptin, and alogliptin (about 150–500 L) but larger for linagliptin (1000–3000 L). All of the DPP-4 inhibitors are recommended as once daily administrations; however, the drugs differ in half-lives and durations of action. The terminal half-lives of alogliptin and sitagliptin are 21 and 12 h, respectively, and their duration of effect approximates this. Saxagliptin, however, has a much longer duration of effect than its half-life of 2.5–3 h would suggest. Linagliptin has a long terminal half-life as well (>100 h); however, accumulation has not been shown clinically. All of the DPP-4 inhibitors except linagliptin are

renally excreted. Linagliptin is eliminated enterohepatically and therefore is the only DPP-4 inhibitor that is safe in renal impairment [11, 12].

Amylin Analogs

Pramlintide is the only amylin analog available and is marketed under the trade name of SymlinPen. As its name suggests, it is available only as a subcutaneous injection and is to be used in conjunction with prandial insulin [13]. Dosing differs depending on whether a patient has type 1 or type 2 diabetes mellitus (30–60 mcg or 60–120 mcg, respectively) and is to be injected immediately prior to major meals. Bioavailability is approximately 30–40%. Time to peak plasma is 20 min, and the half-life is 50 min following single injection. Pramlintide is approximately 60% protein bound and is eliminated renally. No dosage adjustments are suggested for patients with renal failure, but pramlintide has not been studied in patients with end-stage renal disease [14].

Sodium Glucose Cotransporter 2 Inhibitors (SGLT2 Inhibitors)

Currently available SGLT2 inhibitors include canagliflozin (Invokana), dapagliflozin (Farxiga), and empagliflozin (Jardiance). These medications are taken orally once daily. Therapeutic doses are 50–300 mg/day for canagliflozin, 5–10 mg/day for dapagliflozin, and 10–25 mg/day for empagliflozin. Canagliflozin is 65% bioavailable, whereas dapagliflozin about 80% bioavailable. All of the SGLT2 inhibitors are highly protein bound (86% for empagliflozin, where canagliflozin and dapagliflozin are 99% and 91%, respectively). For all of the SGLT2 inhibitors, peak plasma is within 1–2 h and the half-life is about 13 h. SGLT2 inhibitors are either excreted unchanged in the urine or feces or glucuronidated to inactive metabolites, which are then eliminated in feces or urine. 33% of canagliflozin is excreted in the urine. Dapagliflozin and empagliflozin have a higher percentage of

Fig. 3 Cellular and molecular regulation of insulin secretion. The cellular events leading to insulin secretion start with a rise in blood glucose level, which quickly leads to glucose uptake into pancreatic β -cells. Glucose in the cells then undergoes glycolysis and TCA cycle to produce ATP, resulting in an increased ATP/ADP ratio and consequent closure of K_{ATP} -channels. Membrane depolarization from K_{ATP} -channel closure opens L-type calcium channels, allowing calcium influx into the cells and the rise in

intracellular calcium levels. Calcium, mediated at least in part by synaptotagmin-7, then triggers insulin granule exocytosis and the release of insulin into blood. Many of the steps leading to insulin secretion are regulated by metabolic and neurohormonal signals. *GluT-2* glucose transporter 2, *TCA* tricarboxylic acid cycle, *Syt7* synaptotagmin-7, *K-ATP* ATP-sensitive potassium channel, *L-Ca* L-type calcium channel (From Shahidul Islam M [ed]: Calcium Signaling, Springer, 2012, with permission)

urinary excretion (75% and 54%, respectively) and therefore are not recommended for use if GFR is <60 L/min for dapagliflozin and <45 L/min for empagliflozin [15–17].

Pathophysiology

Insulin

In an individual with a normally functioning pancreas, endogenous insulin secretion (i.e., the exocytosis of secretory granules from pancreatic β cells) depends primarily on and is inversely related to the blood glucose concentration [1, 2]. It is influenced to a lesser degree by other nutrients, gastrointestinal hormones, and the autonomic nervous system. Increases in plasma glucose, amino acid, fatty acid, and ketone concentrations; the release of gastrointestinal inhibitory peptide, glucagon-like peptide-1, enteroglucagon, cholecystokinin, gastrin, gastrin-releasing peptide, secretin, and vasoactive intestinal peptide; and vagal stimulation, all of

which occur after the ingestion of glucose or other foods, promote insulin secretion. β_2 -Adrenergic receptor stimulation enhances insulin secretion, whereas α_2 -adrenergic receptor stimulation inhibits it. Hormonal and vagal effects explain why oral glucose is a more potent stimulant of insulin secretion than intravenous glucose is.

Insulin secretion ultimately is triggered by a rise in the intracellular concentration of calcium in response to the generation of adenosine triphosphate (ATP), primarily by the oxidation of glucose but also by the metabolism of other nutrients. It is thought that ATP binds to and blocks the pore-forming unit of ATP-sensitive and voltage-sensitive potassium channels in β -cell membranes. This activity inhibits potassium efflux, with consequent membrane depolarization leading to activation of voltage-sensitive calcium channels and the influx of calcium. Hormones and adrenergic receptors seem to potentiate or antagonize the action of glucose by stimulating or inhibiting adenylyl cyclase, increasing or decreasing intracellular cyclic adenosine monophosphate and calcium concentrations (Fig. 3).

Insulin lowers the serum glucose concentration by facilitating glucose uptake by the liver, myocardium, skeletal muscle, and adipose tissue and by inhibiting hepatic gluconeogenesis and glycogenolysis. Glucose enters cells by diffusion that is facilitated by a family of at least six distinct membrane glycoproteins that are known as glucose transporters (GLUT). Insulin stimulates glucose uptake by promoting the translocation of intracellular vesicles that contain GLUT (subtypes 1 and 4) to the cell membrane and by enhancing the synthesis of GLUT4. It first binds to insulin receptors, membrane glycoproteins that are ligand-activated tyrosine kinases, with consequent enzyme activation. The intervening cascade of events is not well characterized. Other actions of insulin are mediated, at least in part, by its ability to bind and stimulate insulin-like growth factor (IGF) receptors, particularly IGF-1 (also called *somatomedin C receptors*).

In excessive doses, insulin can cause hypoglycemia. Hypoglycemia inhibits endogenous insulin secretion and stimulates the secretion of a variety of counterregulatory hormones, most notably glucagon but also cortisol, epinephrine, estrogens, growth hormone (somatotropin), norepinephrine, somatostatin, and thyroid hormones. Epinephrine and norepinephrine contribute to the autonomic (sympathetic nervous system) symptoms of hypoglycemia (see later), and glucagon may be responsible for the Somogyi phenomenon (morning hyperglycemia after an episode of nocturnal hypoglycemia). Other counterregulatory hormones seem to have only a permissive role during recovery from hypoglycemia. Central nervous system manifestations of hypoglycemia are due to decreased cellular metabolism resulting from the lack of glucose (neuroglycopenia), an essential, and nearly exclusive, energy substrate for brain tissue, which is unable to synthesize glucose.

Sulfonylureas

Sulfonylureas enhance the secretion of insulin in response to increases in blood glucose [1–3] (Fig. 4). They bind to a distinct “sulfonylurea

receptor” site associated with ATP-sensitive and voltage-sensitive potassium channels on the β -cell membrane with consequent blocking of these channels, inhibition of potassium efflux, membrane depolarization, calcium influx, and insulin secretion. Extrapankreatic effects (e.g., decreased hepatic gluconeogenesis and insulin clearance, increased peripheral insulin sensitivity, stimulation of somatostatin secretion, and suppression of glucagon secretion) are thought to be clinically insignificant. Toxic effects are secondary to hyperinsulinemic hypoglycemia.

Meglitinides

Similar to the sulfonylureas, these agents bind to receptors on the β -cell membrane with consequent blocking of potassium channels, membrane depolarization, opening of calcium channels, and insulin secretion in response to increases in blood glucose [5, 6]. Toxic effects are due primarily to hyperinsulinemia and subsequent hypoglycemia.

Biguanides

Antihyperglycemic effects are due to enhanced peripheral glucose uptake and inhibition of hepatic gluconeogenesis [1–3, 8]. Metformin promotes glucose uptake by increasing the binding of insulin to its receptor and by increasing the synthesis and intracellular translocation of glucose transporters, such as GLUT-1 (also known as SLC2A1). It also enhances the tyrosine kinase activity of insulin receptors, promoting the uptake of glucose by skeletal muscle. Despite being used clinically for many years, the exact mechanism of action is not yet fully understood. Newer evidence suggests that metformin also inhibits complex I in the mitochondrial electron transport chain and that by lowering ATP levels in the mitochondria, AMP accumulates, thus disrupting the activity of enzymes in gluconeogenesis pathway, and inhibiting the body’s response to glucagon [18]. Although insulin (endogenous or exogenous) is required for metformin to be

Fig. 4 Closure of the pancreatic β -cell type K_{ATP} channel by ATP and sulfonylurea. Increased ATP caused by glucose metabolism closes the K_{ATP} channel by binding to the Kir6.2 subunit (a). Sulfonylureas close the channel by binding to the SUR1 subunit (b). The SUR2 subunit has binding sites for benzamide-derivatives in addition to sulfonylureas (SU). Although there are four binding sites for the ATP molecule and four binding sites for the sulfonylurea molecule in each channel complex, occupation of only one of these sites by ATP or sulfonylurea is sufficient to close the channel (Offermanns S and Rosenthal W [eds]: Encyclopedic Reference of Molecular Pharmacology, Springer, 2004, with permission)

effective, insulin levels are not affected, and hypoglycemia does not occur with metformin monotherapy or overdose.

Metformin associated lactic acidosis has also been fairly poorly understood, but now thought to be secondary to inhibition of complex I of the respiratory chain in addition to likely inhibiting various enzymes in the entry point from the glycolysis pathway in the citric acid cycle [19]. Higher metformin doses (as in overdose) and renal insufficiency are risk factors for development of this disorder. Therefore, any drugs which have potential to compromise renal function may precipitate this condition (aminoglycosides, iodinated radiographic contrast material, for example). In addition, medications which inhibit the organic cation transporter-2 (including cetirizine, trimethoprim) in the proximal tubules of the kidney may inhibit metformin secretion, causing build up of the drug and thereby precipitating lactic acidosis.

Thiazolidinediones

Thiazolidinediones primarily act by decreasing insulin resistance in adipose tissue, liver, and skeletal muscle, potentiating the effects of hypoglycemic agents [3, 20, 21]. They also decrease hepatic gluconeogenesis and have favorable effects on other risk factors for cardiovascular disease (e.g., blood pressure, fibrinolysis, lipid profile). However, there is ongoing concern that thiazolidinediones increase risk of heart failure, fracture, and weight gain. Stimulation of peroxisome proliferator-activated receptors, primarily the gamma subtype, which enhances the transcription of insulin-responsive genes involved in the control of glucose transport, use, and production (and in the regulation of fatty acid metabolism), is the underlying mechanism. Because thiazolidinediones enhance the effects of insulin, insulin and C peptide plasma concentrations are reduced, and hypoglycemia is not expected to occur with

monotherapy or overdose. Liver toxicity has been reported in therapeutic doses of rosiglitazone, troglitazone, and pioglitazone.

α -Glucosidase Inhibitors

α -Glucosidase inhibitors competitively and reversibly inhibit membrane-bound α -glucosidase, glucoamylase, maltase, and sucrase, enzymes that hydrolyze oligosaccharides (dextrins, maltose, maltotriose, and sucrose) to glucose in the brush border of the small intestine. This activity delays and partially decreases the absorption of glucose [3]. Acarbose also inhibits pancreatic α -amylase, which hydrolyzes ingested polysaccharides, such as amylose and amylopectin, or starch, to oligosaccharides. Although neither agent significantly inhibits lactase, the resultant malabsorption of nonlactose carbohydrates can result in gastrointestinal symptoms that are identical to those of lactase deficiency. Taken alone, α -glucosidase inhibitors do not cause hypoglycemia. Acarbose has been linked to elevated serum aminotransferase concentrations, which resolve upon discontinuation of the medication. Overdose of these medications would be expected to cause gastrointestinal upset, such as abdominal pain, bloating, diarrhea, and cramping.

GLP-1 Agonists and DPP-4 Inhibitors

GLP-1 is an incretin hormone, which is released from gastrointestinal L-type cells in response to an oral glucose load [10]. This hormone promotes insulin release from the pancreatic islet cells. In addition to insulin release, the hormone also delays gastric emptying, decreases food intake, improves insulin sensitivity, decreases postprandial glucagon secretion, and promotes synthesis of insulin (Fig. 5). GLP-1 is metabolized very quickly and is therefore therapeutically ineffective. GLP-1 agonists, however, are resistant to degradation. DPP-4 inhibitors and GLP-1 agonists have similar effects on blood glucose, as DPP-4 is responsible for degradation of GLP-1. The GLP-1 agonists and DPP-4 inhibitors are not expected to cause hypoglycemia as monotherapy

in therapeutic doses. These agents are not well studied in overdose and therefore information regarding acute overdose is limited to case reports. Report of an overdose of 90 μ g of exenatide did not result in hypoglycemia [22]. However, accidental administration of 10 times the normal dose of exenatide in a phase III clinical trial did result in hypoglycemia [23]. The actual glucose concentration is not reported. There are also reports of hypoglycemia associated with neteglinide and repaglinide overdose [24]. A recent review on clinical effects of exposures to DPP-4 inhibitors showed a rare incidence of clinically significant hypoglycemia in both intentional and accidental exposures [25].

Amylin Analogs

Pramlintide is an injectable synthetic amylin analog. Amylin is a 37 amino acid peptide, which is stored in pancreatic beta cells and released with insulin. Amylin and insulin have complementary effects, which is why pramlintide is used in conjunction with insulin therapy. Amylin works to regulate postprandial glucose serum concentrations by promoting satiety, delaying gastric emptying, and decreasing postprandial glucagon release [13, 26]. As this medication is added to insulin therapy, patients are at risk for hypoglycemia even with therapeutic doses, especially in the first 4 weeks of instituting therapy [27].

SGLT-2 Inhibitors

Sodium glucose cotransporter 2 inhibitors decrease plasma glucose by enhancing renal glucose excretion. About 90% of glucose is reabsorbed in the renal proximal tubules by SGLT2. The remaining 10% is then reabsorbed in the distal tubules by SGLT1. By inhibiting SGLT2, plasma glucose is decreased by increasing glucose in urine. Hypoglycemic episodes in conjunction with other antidiabetic agents have been reported. There is evidence that use of these medications increases risk of urinary tract infections as well as fungal vaginal infections.

Fig. 5 Physiology of DPP-4 inhibitors

(Courtesy of Wikipedia under Creative Commons)

Some of these infections have been life threatening [28, 29]. Many cases have been reported of patients taking prescribed doses of SGLT2 inhibitors and subsequently develop ketoacidosis with only mildly elevated plasma glucose. One case reported a patient on canagliflozin who presented with hypernatremia and hypercalcemia, likely from osmotic diuresis and subsequent dehydration [30]. The US Food and Drug Administration issued safety alerts in 2015 warning of the risks of ketoacidosis, urinary infections, and fractures (secondary to decreased bone mineral density) in patients taking SGLT2 inhibitors [31, 32].

Clinical Presentation

Hypoglycemia

Hypoglycemia, the hallmark of poisoning by insulin, sulfonylureas, and meglitinides, may result from therapeutic doses of these agents in nondiabetics and excessive doses in diabetics [33–36]. Accidental poisoning may occur after therapeutic dosing in individuals with diabetes who miss a meal or eat at a time that does not correspond to that of peak drug effects; increase their dose of a hypoglycemic agent or physical activity; change agents, formulations, or brands; or have another antidiabetic drug added to their therapeutic regimen. Agents without intrinsic hypoglycemic activity also can precipitate hypoglycemia when added to existing antidiabetic

therapy (Table 4). Predisposing factors include congestive heart failure; renal insufficiency; malignancy; sepsis; and conditions associated with limited glycogen reserves, such as extremes of age, malnutrition, and advanced liver disease [37].

Accidental poisoning also may result from dispensing errors (wrong drug or wrong dose). Poor handwriting and sound-alike drug names (e.g., chlorpropamide/chloroquine/chlorpromazine, Diabinese/Diamox, Tolinase/Tolactin) are responsible for some medication errors. Neonatal hypoglycemia can result from maternal drug exposure. As for all other agents, poisoning can occur in young children as a consequence of accidental ingestion, an innocent exploratory behavior in this age group.

Nonaccidental self-poisoning usually occurs in depressed, suicidal individuals but also may be encountered in individuals with factitious disorder. Factitious hypoglycemia can involve anyone who has access to hypoglycemic agents, such as diabetics, relatives of diabetics, and health care workers [38]. Difficult-to-diagnose but rare presentations of antidiabetic agent poisoning include attempted homicide and factitious disorder imposed on another [39]. A puncture wound, boggy skin, skin discoloration, and tenderness may be noted at the site of an insulin injection [40].

Autonomic manifestations of hypoglycemia include anxiety, diaphoresis, hunger, nausea and vomiting, palpitations and tachycardia,

Table 4 Agents that can cause hypoglycemia^a

Agent	Mechanism
Akee fruit (unripe)	Inhibition of gluconeogenesis by hypoglycin
	A toxin
Anabolic steroids	Enhanced peripheral insulin effect
ACE inhibitors	Inhibition of catecholamine release/effects
β_2 -agonists	Enhanced insulin secretion
β -blockers	Inhibition of catecholamine effects
Bromocriptine	Inhibition of growth hormone secretion/catecholamine effects
Calcium	Enhanced insulin secretion
Clofibrate	Enhanced peripheral insulin effect
Disopyramide	Unknown
Ethanol	Inhibition of gluconeogenesis
Lidocaine	Unknown
Lithium	Unknown
NSAIDs ^b	Unknown
Para-aminobenzoic acid	Unknown
Pentamidine	Destruction of pancreatic β cells with release of insulin
Propoxyphene	Unknown
PNU	Destruction of pancreatic β cells with release of insulin
Quinidine/quinine	Enhanced insulin secretion
Salicylates ^b	Enhanced insulin secretion and peripheral insulin effect
Streptozocin	Destruction of pancreatic β cells with release of insulin
Sulfonamides ^b	Unknown

ACE angiotensin-converting enzyme, NSAIDs nonsteroidal antiinflammatory drugs, PNU N-3-pyridylmethyl-N'-p-nitrophenylurea, Vacor

^aOther agents, implicated on the basis of isolated case reports, include chlorpromazine, cocaine, haloperidol, orphenadrine, para-aminosalicylic acid, sulfapyrazone, and valproate

^bThese and other highly protein-bound agents, such as warfarin and phenytoin, also can enhance the effect of sulfonylureas by decreasing the protein binding of sulfonylureas

tachypnea, paresthesias, tremors, and peripheral vasoconstriction with pallor and widening of the pulse pressure [33–36, 41–45]. As mentioned previously, multiple bioamines can be heightened or activated in the setting, such as norepinephrine and epinephrine. The absence of autonomic findings does not preclude a diagnosis of

hypoglycemia, however, particularly in patients who are taking medications with sympatholytic activity, such as β -blockers, clonidine, and prazosin, and in patients with long-standing diabetes who may have impaired autonomic function and counterregulatory hormone responses.

Tachydysrhythmias, primarily atrial fibrillation and premature atrial and ventricular beats but also atrial flutter; supraventricular, junctional, and ventricular tachycardia (monomorphic and polymorphic); and ventricular fibrillation have been reported [46, 47]. Electrocardiographic manifestations also include T-wave flattening and increases in the QT interval and QT dispersion [48]. ST segment depression also has been described [49]. Repolarization effects seem to be common yet subtle and often go unrecognized. These effects are thought to promote tachydysrhythmias and, similar to other autonomic effects, ultimately result from the action of counterregulatory hormones (primarily epinephrine) [50]. Tachydysrhythmias may be responsible for many cases of sudden, unexplained death in diabetics, particularly patients with early autonomic neuropathy, which results in sympathetic hyperactivity [51]. Bradycardia and heart block also can occur, but bradydysrhythmias seem to be much less common than tachydysrhythmias [52]. Both fetal bradycardia and tachycardia have been attributed to maternal hypoglycemia [41, 53]. Hypoglycemia also has been associated with congestive heart failure, worsening heart failure, and sudden death in patients with heart failure, but in most cases, it is not clear that a causal relationship exists [37, 54].

Prolonged (>1 h) hypoglycemia may lead to hypothermia [55, 56]. Neonates and infants also seem to be particularly susceptible to hypothermia. Less commonly, sympathetic hyperactivity secondary to hypoglycemia may cause hyperthermia. Other complications include respiratory failure and adult respiratory distress syndrome [57]. Cyanosis and respiratory failure have been noted in newborns and infants. Metabolic abnormalities commonly associated with hypoglycemia include hypokalemia; hypomagnesemia; hypophosphatemia [58]; and, rarely, hyponatremia, hypocalcemia, and metabolic acidosis. Serum insulin concentrations are always inappropriately high.

Neuroglycopenia initially causes impaired cognitive function manifested as altered affect, perception, and personality; difficulty with calculations, concentration, memory, and speech; and delirium [33–36, 41–45]. Ataxia, blurred vision, dizziness, fatigue, headache, generalized weakness, and malaise also may be noted. Neonates, infants, and young children may exhibit irritability and feeding problems. If neuroglycopenia persists, progressive deterioration in the level of consciousness occurs, with manifestations ranging from agitation and seizures to lethargy and coma, with or without focal findings [59–62]. Seizures may be single or recurrent and focal or generalized. Both brief and prolonged postictal periods have been described. Coma may be associated with decerebrate posturing, but brainstem reflexes, such as oculocephalic, oculovestibular, and pupillary reflexes, are usually preserved. Hemiplegia, with or without coma, and choreoathetosis also can occur. With prompt treatment, complete recovery is expected, but prolonged neuroglycopenia may result in permanent neurologic damage (e.g., cognitive dysfunction, cranial nerve palsies, cerebral infarction, coma, recurrent seizures, or death).

The time of onset and duration of hypoglycemia depend on the agent and dose involved. They also depend on the baseline glucose and the presence or absence of insulin antibodies and insulin resistance, with insulin-dependent diabetics tending to be less susceptible than nondiabetics to a given dose. Hypoglycemia after usual or slightly greater doses of insulin would be expected to begin around the time of peak effect of a therapeutic dose (see Table 4) [58]. Because insulin typically is administered in the morning and late afternoon or evening, hypoglycemia most commonly occurs between noon and supertime (from the morning dose) and during the late night or early morning hours (from the afternoon/evening dose). Larger doses likely would result in an earlier onset. Delayed onset of hypoglycemia also has been reported (23 h for regular insulin, 30 h for NPH insulin, and 44 h for Lente insulin) [63]. The duration of action seems to be dose related, with persistent or recurrent hypoglycemia lasting up to 6 days after massive insulin overdose

[64]. Although serum insulin concentrations do not seem to correlate with the severity of hypoglycemia, they do correlate with its duration, with hypoglycemia persisting until insulin concentrations return to normal [64, 65].

The incidence of hypoglycemia during sulfonylurea therapy seems to be related to the half-life of the agent involved, occurring more frequently with agents that have longer half-lives. In this setting, hypoglycemia most commonly occurs in the afternoon. In children with accidental sulfonylurea ingestions, the time of onset of hypoglycemia ranges from 0.5–16 h, with 50% occurring within 2 h and 96% occurring within 8 h, and a single tablet is potentially toxic [66, 67]. Data based on dispensing errors indicate that therapeutic doses also are potentially toxic in nondiabetic adults, but hypoglycemia sometimes may not occur until after the second or third dose. A single or extra therapeutic dose is unlikely to cause hypoglycemia in an adult diabetic. Although patients with intentional overdose often present with hypoglycemia long after ingestion (up to 48 h) [68], the maximal interval between ingestion and symptom onset in these patients is unclear. The duration of hypoglycemia seems to be dose related and typically ranges from hours to several days, although a case lasting 27 days has been reported [69].

Metformin Associated Lactic Acidosis

Metformin associated lactic acidosis may occur acutely after large intentional overdose in adults [70–73]. More commonly, this complication occurs when a therapeutic dose is increased or patients on long-term therapy develop conditions that decrease drug or lactate metabolism or increase lactate production (as in severe illness or sudden decrease in GFR) [19, 74–76]. In these settings, onset typically is insidious. Symptoms are nonspecific and include anorexia, lethargy, nausea, vomiting, diarrhea, thirst, and abdominal pain. Hyperpnea and signs of dehydration, hypoxia, or shock may be present. Laboratory evaluation reveals an increased anion gap metabolic acidosis with elevated plasma lactate

(>5 mEq [or mmol]/L) [74]. Ketosis (of unclear origin) may or may not be present [75, 77]. Mortality of this condition is certainly improving but still quite high and reported to be about 50% [78].

Diagnostic Considerations

Although a blood glucose concentration of less than 70 mg/dL (3.9 mmol/L) is considered low, clinical hypoglycemia requires the presence of symptoms. Whipple's triad [43–46, 79] for the diagnosis of hypoglycemia consists of low blood glucose, symptoms of hypoglycemia, and improvement after glucose administration. There are situations of clinical hypoglycemia, however, in which these criteria are not met, including the empirical administration of glucose when a blood sample cannot be obtained and failure to respond to glucose because irreversible neurologic damage has occurred. Patients with serious sulfonylurea toxicity may also not respond to intravenous glucose therapy alone [68, 80].

Signs and symptoms of hypoglycemia usually occur when the serum glucose level decreases to 40–45 mg/dL (2.2–2.5 mmol/L), but there is substantial individual variation. Although autonomic manifestations typically precede manifestations of neuroglycopenia, diabetics with autonomic neuropathy may be asymptomatic until symptoms of neuroglycopenia develop. Women tend to be asymptomatic at lower blood glucose concentrations than men, and children tend to be asymptomatic at lower values than adults. Symptoms are more likely to occur when glucose concentrations decrease rapidly or by a large amount and depend on the baseline glucose value. Symptoms can occur in diabetics with normal or even elevated glucose levels if they are accustomed to a higher baseline level and experience a rapid decline in their glucose concentrations. Conversely, when glucose levels slowly decline, such as with prolonged fasting, symptoms may be absent despite glucose levels of 20–30 mg/dL (1.1–1.6 mmol/L) [81] because high levels of free fatty acids and ketone bodies provide alternative energy substrate.

Table 5 Medical conditions that can cause hypoglycemia

Decreased glucose availability
Decreased glucose absorption: diarrhea, malabsorption syndromes
Decreased glucose intake: fasting, acute or chronic malnutrition due to illness or starvation, vomiting
Inability to synthesize glucose: inborn errors of metabolism (gluconeogenic enzyme deficiency)
Inability to synthesize, store, or metabolize glycogen: inborn errors of metabolism (glycogen synthesis and glycogenolysis enzyme deficiency, glycogen storage diseases), liver disease (especially acute hepatic failure, Reye's syndrome), end-stage renal failure
Increased glucose utilization
Deficiency of counterregulatory hormones: adrenal, pancreatic, pituitary, and thyroid disease
Increased insulin activity or secretion: insulin antibodies with insulin-like activity (pseudohyperinsulinemia), pancreatic β -cell adenoma (insulinoma) or ductal overgrowth (neonatal nesidioblastosis), reactive hypoglycemia (dumping syndrome, postprandial)
Increased metabolic demands: fever/sepsis, large tumor loads, pregnancy
Lack of alternative energy sources: decreased fat stores (malnutrition), inability to metabolize or mobilize fat (carnitine deficiency)

The differential diagnosis of hypoglycemia includes nonantidiabetic drug exposure (see Table 4) [34–36], a variety of medical conditions (Table 5), and antidiabetic agent poisoning. Direct inspection of all prescribed pills and independent confirmation of their identity by imprint code may disclose a medication error. Failure of the blood glucose concentration to normalize after intravenous glucose administration is usually a consequence of severe sulfonylurea poisoning [68, 81]. The presence of low birth weight and other metabolic abnormalities (e.g., high lactate acidemia or high free fatty acid levels, ketosis) in a neonate suggests an inborn error of metabolism [82]. Although virtually any neurologic manifestation, including focal findings, is consistent with a diagnosis of hypoglycemia, failure of the dysfunction to respond to normalization of the blood glucose concentration should prompt evaluation (e.g., computed tomography scan, lumbar puncture) for conditions such as central nervous system infarction, infection, or hemorrhage.

After clinical evaluation, if the cause of hypoglycemia is not apparent, measurement of serum insulin, C peptide, and proinsulin levels and toxicology testing may be helpful [37]. To interpret hormone levels properly, samples must be obtained at the time of hypoglycemia. Insulin secretion normally is suppressed and insulin and C peptide levels are low when hypoglycemia is present. When hypoglycemia is due to exogenous insulin or to oral hypoglycemics and other agents and conditions that enhance endogenous insulin secretion (see Tables 4 and 5), however, serum insulin concentrations are elevated. Except with exogenous insulin exposure, C peptide also is elevated. An alternative, more sophisticated approach is to determine the molar ratio of insulin to C peptide [83]. Because C peptide has a longer half-life than insulin, this ratio is less than 1, unless exogenous insulin has been administered. This relationship seems to hold for patients with renal failure, who may have abnormally high baseline levels of insulin and C peptide, but not for diabetics who have insulin antibodies, which can elevate insulin levels falsely. Diabetics with insulin antibodies who have insulin-like activity (i.e., autoimmune hypoglycemia) have low C peptide levels, whereas diabetics with insulin antibodies who lack such activity (e.g., diabetics with insulin resistance) have elevated C peptide levels [84].

Proinsulin levels also are elevated when hypoglycemia is due to enhanced endogenous insulin secretion [85]. Insulinomas can be differentiated from other causes by the presence of an increased ratio of proinsulin to insulin. Although sulfonyleurea overdose also can produce these findings, proinsulin levels are not nearly as high as they are with insulinomas. An inappropriately low level of IGF-1 binding protein [86] and exaggerated insulin [87] and glycemic (>30 mg/dL increase in blood glucose level) [88] responses to glucagon also are seen in patients with endogenous hyperinsulinemia.

Detection of oral hypoglycemic agents and measurement of insulin concentration require sophisticated laboratory methods and therefore are not routinely available. For the laboratory investigation of potential antidiabetic agent

poisoning, it is advisable to consult with laboratory personnel to determine the appropriate specimen (blood or urine) and test for detecting or measuring the suspected agent or agents involved.

Treatment

Hypoglycemia

Although standard life-support measures sometimes may be required, increasing the blood glucose level is often all that is necessary when hypoglycemia is the underlying cause of physiologic derangement. This is the rationale for performing a rapid bedside glucose determination or empirically administering glucose in patients with altered mental status, the hallmark of neuroglycopenia. Supportive care also should include correction of fluid and electrolyte abnormalities.

Indications for ICU Admission in Antidiabetic Agent Poisoning

Patients with unstable vital signs or unstable cardiac rhythm and evidence of myocardial ischemia or acute infarction associated with hypoglycemia

Patients with neurologic dysfunction that persists despite normalization of the blood glucose and for those with significant acidemia owing to metformin poisoning

Note:

ICU admission is not routinely indicated for the monitoring of asymptomatic patients with a history of antidiabetic agent overdose and the monitoring and treatment of those with reversible hypoglycemia, but it may be necessary if continuous observation, frequent blood testing for glucose and other analytes, and therapy for hypoglycemia cannot be provided elsewhere.

Cardiac monitoring is not routinely necessary for patients who are asymptomatic or have reversible hypoglycemia, but it may be appropriate for those with underlying cardiovascular disease.

The preferred treatment for hypoglycemia is sucrose or dextrose (D-glucose). (Grade II-1 recommendation) Dextrose can be given orally to patients who are awake and cooperative. Chewable 4-g tablets and gels containing 15 g of dextrose are available. The usual adult dose is 10–20 g. Alternatively, candy or a cup of fruit juice with several teaspoons of added sugar can be given [89]. Table sugar (sucrose) may not be effective, however, for patients taking α -glucosidase inhibitors. Oral glucose solutions should not be given to patients who lack adequate protective airway reflexes.

Intravenous dextrose is necessary for patients who cannot take it orally. Dextrose is available in a variety of formulations, with 50-mL ampoules of 10%, 25%, and 50% solutions (i.e., D10, D25, and D50) containing 5, 12.5, and 25 g of dextrose, respectively, being the most common. The 50% solution can be used in adults and children, but lower concentrations are recommended for infants and neonates. The goal of therapy is to increase the serum glucose to normal levels (70–110 mg/dL [3.9–6.1 mmol/L]). Care should be taken not to overtreat because hyperglycemia stimulates endogenous insulin secretion and promotes recurrent hypoglycemia. This phenomenon of rebound hyperinsulinemia after glucose administration, which has been well documented in sulfonylurea poisoning [68], also seems to occur after insulin overdose [90]. It can lead to a vicious cycle of alternating hyperglycemia and hypoglycemia, making treatment unduly complicated. In addition, there are wide individual variations in the magnitude of rise in serum glucose in response to a given dose of intravenous dextrose [91, 92]. Except in prolonged neuroglycopenia resulting in permanent brain damage and in severe sulfonylurea poisoning, return to normal mental status can be expected to occur rapidly (within seconds to minutes of dextrose administration). If this does not occur either prolonged hypoglycemia has been present or there is an unrelated cause for the hypoglycemia.

It is important that proper functioning of the intravenous line be confirmed before administering intravenous dextrose because these solutions

are extremely hypertonic (2525 mOsm/L for D50) and can cause tissue necrosis if extravasation occurs. They also can cause vein irritation, with pain, phlebitis, and venous thrombosis. Rapid administration also can cause hyperosmolality and consequent central nervous system dysfunction. For these reasons, slow injection is preferred. Other potential complications include fluid overload, hypokalemia, hypophosphatemia, and hypomagnesemia. In patients who are at high risk for Wernicke's encephalopathy (e.g., alcoholics and malnourished patients), concomitant administration of intravenous thiamine is prudent.

If an intravenous line cannot readily be established, intramuscular or subcutaneous glucagon, 1 mg for adults and children weighing more than 20 kg and 0.5 mg for children weighing less than 20 kg, can be given [1–3, 93]. (Grade I recommendation) Glucagon increases serum glucose by enhancing glycogenolysis. Clinical effects are slower in onset than they are with intravenous dextrose, with return to normal mental status occurring in 5–20 min. [94] Glucagon may be ineffective if hepatic stores of glycogen are diminished (e.g., in malnourished patients). Because effects may be transient, supplemental glucose should be given subsequently. Glucagon, like glucose, stimulates insulin secretion and can promote recurrent hypoglycemia, especially in the context of sulfonylurea ingestion or insulinoma [95]. Vomiting is a relatively common side effect.

Patients who respond to dextrose or glucagon then should be fed a meal. Diabetics with therapeutic misadventures involving insulin or an antihyperglycemic agent are unlikely to experience recurrent hypoglycemia and can be discharged, provided that they can monitor their blood glucose at home and have a responsible third party stay with them. Medication dosage adjustment also may be necessary. Patients with intentional insulin overdose and intentional or unintentional oral hypoglycemic agent exposure are at risk for delayed or recurrent hypoglycemia and require prolonged and frequent or continuous clinical monitoring with hourly blood glucose determinations, which generally can be

accomplished only in an emergency, intermediate, or intensive care unit setting. Little is known about GLP-1 agonist, DPP-4 inhibitor, pramlintide, and SGLT2 inhibitor overdose. For this reason, it is suggested to admit these patients until more data can be gathered.

Recurrent hypoglycemia can be treated initially with an intravenous bolus of dextrose as described earlier. If needed, a continuous infusion of D₁₀W also can be used, starting at a basal glucose requirement rate of about 0.1 g/kg/h or 1 mL/kg/h and adjusted upward as necessary [91]. However, in sulfonylurea overdose specifically, this therapy may not be successful as most of these patients will have intact pancreatic function. In these patients, after a glucose bolus is administered, insulin is secreted, contributing to another hypoglycemic episode. Therefore, after the initial IV bolus of dextrose for symptomatic sulfonylurea overdose, treatment with octreotide (Sandostatin) is expected to be more effective than dextrose infusions [96]. (Grade I recommendation)

Octreotide is a synthetic analogue of the naturally occurring pituitary gland hormone somatostatin [1, 3]. Similar to somatostatin, it regulates the function of the pituitary gland, pancreas, and intestine by inhibiting the secretion of insulin, glucagon, and other hormones from these organs (see ► Chap. 156, “Octreotide” for greater detail of the clinical pharmacology of this agent). To treat oral hypoglycemic poisoning, octreotide usually is given subcutaneously in a dose of 50 µg every 6 h. Continuous infusions also have been used. When used in this setting, no significant side effects have been reported.

Diazoxide is a vasodilator antihypertensive agent that is related structurally to thiazide diuretics and has also been used for oral hypoglycemic overdose [1, 3]. Tachycardia and orthostatic hypotension are common with diazoxide use. The other main side effect of diazoxide, sodium and water retention, could add to the free water effects of dextrose therapy.

Octreotide was found to be superior to diazoxide in preventing hypoglycemia in glipizide-poisoned volunteers. It was so effective

that some subjects did not even require supplemental glucose. Given the efficacy of octreotide and side effect profile of diazoxide, octreotide has replaced diazoxide therapy in acute oral hypoglycemic overdose. In the same study, dextrose requirements were shown to be similar when treated with diazoxide or dextrose infusion alone and both treatment arms measured high levels of insulin in the poisoned patients. Therefore, with the limited evidence available, it is not recommended that diazoxide be used when octreotide is unavailable as it is likely similarly efficacious to dextrose infusion and has unwanted side effects [80, 97].

When a second episode of hypoglycemia occurs, more episodes are likely. Because the risk of recurrence and the duration of risk are variable and unpredictable, however, the optimal duration of insulin secretion inhibitor therapy is unknown. One approach is an initial treatment period of 24 h followed by close monitoring for hypoglycemia for another 12–24 h, because delayed recurrence of hypoglycemia has been reported after such therapy [97, 98]. Should another episode of hypoglycemia occur, reinstitution of treatment for an additional 24 h should be considered.

Measures to prevent drug absorption and enhance drug elimination also should be considered. Gastric decontamination measures may be appropriate for acute oral overdoses involving hypoglycemic agents and metformin. Activated charcoal adsorbs sulfonylureas [99]. However, there are no data indicating that activated charcoal administration alters the outcome in these patients. It is unlikely that activated charcoal will have a significant effect on drug absorption if given greater than 1 hour post-ingestion [100]. Surgical excision of tissue from the site of injection of insulin overdose has been reported [101, 102], but the efficacy of this intervention is anecdotal, and the necessity of performing it remains questionable due to the inherent risks and invasiveness of such a procedure. Urinary alkalization will enhance the elimination of chlorpropamide [103]. Therefore, it should be

considered in order to shorten time-course of poisoning. This exceedingly rare event should be done so with proper supportive care and treatment of hypoglycemia as above [104].

Metformin-Associated Lactic Acidosis

The treatment of metformin poisoning is primarily supportive [19, 73, 75]. Intravenous saline can be given to correct dehydration, with caution not to cause fluid overload in patients with decreased urinary output. Intravenous saline also should enhance the elimination of metformin, but the efficacy of inducing diuresis for this purpose, although theoretically attractive, has not been proven. Hemodialysis is indicated for refractory acidosis. It also is effective in removing lactate, pyruvate, and ketones and as supportive therapy for uremia. Recently published workgroup recommendations outline indications for extracorporeal treatment, which are as follows: lactate concentration greater than 20 mmol/L, pH less than or equal to 7.0, shock, failure of standard supportive measures, and decreased level of consciousness. The group goes on to recommend that extracorporeal treatment be continued until the lactate concentration is less than 3 mmol/L and pH greater than 7.35. Intermittent hemodialysis is recommended initially, but continuous renal replacement therapies may be considered if hemodialysis is unavailable [19, 71, 105, 106]. (Grade III evidence)

Criteria for ICU Discharge in Antidiabetic Agent Poisoning

Normal vital signs, normal cardiac rhythm, and no sign of hypoglycemia-induced cardiac ischemia

Resolution or stabilization of hypoglycemia-induced neurologic dysfunction

In the case of metformin, resolution of the metabolic acidosis

Common Errors in Antidiabetic Agent Poisoning

Failure to consider the possibility of occult exposure to antidiabetic agents or their surreptitious use in patients with unexplained hypoglycemia, particularly those who are health care workers or relatives of diabetics

Failure to include exposure to nonantidiabetic drugs and potential drug interactions in the differential diagnosis of hypoglycemia

Failure to appreciate that a blood glucose level less than 70 mg/dL (3.9 mmol/L), while statistically abnormal, is not sufficient to make a diagnosis of hypoglycemia; that there is substantial individual variability in the glucose level at which signs and symptoms of hypoglycemia develop; that an abnormally low blood sugar may be seen in asymptomatic individuals, particularly women and children; that some individuals, especially diabetics, may exhibit signs and symptoms of hypoglycemia at normal or even elevated blood glucose levels; and that the administration of glucose solely on the basis of an abnormally low blood glucose level is unnecessary and will obscure the diagnosis of antidiabetic agent poisoning

Failure to appreciate that sulfonylurea-induced hypoglycemia may be delayed in onset and prolonged in duration and that an extended period of observation is required for patients with unintended or excessive exposure to such agents

Failure to appreciate that the oral administration of table sugar and complex carbohydrates may not be effective in treating hypoglycemia in patients taking alpha-glucosidase inhibitors

Failure to appreciate that overzealous treatment of hypoglycemia resulting in hyperglycemia will stimulate insulin secretion and can promote recurrent hypoglycemia, particularly in patients with sulfonylurea poisoning

Key Points in Antidiabetic Agent Poisoning

1. Hypoglycemia, the hallmark of antidiabetic agent poisoning, can result from exposure to hypoglycemic agents, which cause hyperinsulinemia either directly (exogenous insulin) or indirectly by enhancing endogenous insulin release (sulfonylureas, meglitinides, GLP-1 agonists, DPP-4 inhibitors) or to antihyperglycemic agents, which do not cause hypoglycemia when taken alone but which enhance the tissue action of insulin (biguanides and thiazolidinediones) or prevent the intestinal absorption of carbohydrates (alpha-glucosidase inhibitors) and thus potentiate the effect of hypoglycemic agents.
2. Signs and symptoms of hypoglycemia are due to central nervous system dysfunction resulting from the lack of essential energy substrate (neuroglycopenia) and autonomic dysfunction (sympathetic hyperactivity) caused by the effects of counter-regulatory hormones, primarily epinephrine.
3. The magnitude of increase in blood glucose that occurs in response to exogenous glucose administration, the preferred treatment for hypoglycemia, is variable and unpredictable, making it difficult to avoid causing hyperglycemia, a phenomenon that occurs most commonly, but not exclusively, in sulfonylurea poisoning.
4. The administration of octreotide, which inhibits endogenous insulin secretion, can prevent rebound hyperinsulinemia and decrease the incidence of recurrent hypoglycemia resulting from glucose therapy in patients with sulfonylurea-induced hypoglycemia.
5. Metformin, by inhibiting complex I of the mitochondrial electron transport chain, can cause lactic acidosis following acute overdose and under conditions of reduced drug elimination or increased lactate production. Therapy is primarily supportive, with extracorporeal elimination being reserved for refractory acidosis.

Microtubules are present in all eukaryotic cells. They are responsible for movement of vesicles within cells, motion of cilia and flagella, and chromosome separation in mitosis. In neurons, microtubules serve as tracks for protein particles and organelles that move up and down the axon. They also can direct proteins for repair of cellular injury. Antitubulin agents, including colchicine, vincristine, vinblastine, and podophyllin, inhibit the construction of microtubules, which accounts for the therapeutic and the toxic actions of these agents.

Colchicine

Colchicine is an alkaloid derived from *Colchicum autumnale*, a member of the family Liliaceae [1], and from *Gloriosa superba* (glory lilly) [2, 3]. *C. autumnale* is a perennial plant that is known commonly as *autumn crocus*, *wild saffron*, *meadow saffron*, *naked lady*, *naked boy*, and *son before the father*. This plant is indigenous to temperate areas of Europe, Asia, and America. It is unusual because it flowers after the long, lanceolate leaves wither back and fall off (hence the “son before the father”). All parts of the plant contain colchicine, but the highest concentration is in the bulb, which is rooted underground [1]. Accidental and intentional ingestion of *Colchicum autumnale* has led to fatal poisoning despite supportive measures [4, 5]. Intentional ingestion of *Gloriosa superba* has also been reported to result in

significant toxicity that is indistinguishable from poisoning with colchicine [6].

Colchicine has been used since the sixth century A.D., when it was introduced by Alexander of Tralles as a treatment for gout. It is said that Benjamin Franklin also used colchicine as a remedy for his gouty arthritis and possibly introduced it into the United States [1, 7]. Purified colchicine later was isolated from *C. autumnale* tubers in 1820 by Syng Dorsey and became widely known as a treatment for gouty arthritis [2].

In 2009, the US Food and Drug Administration (FDA) approved oral colchicine for the treatment of gouty arthritis, preventing gout attacks, and managing familial Mediterranean fever [8]. Previously, oral colchicine had been used for many years in the United States as an unapproved drug without FDA-approved prescribing information, dosage recommendations, or drug interactions. Over the years, colchicine has also been advocated for pseudogout, sarcoidosis [9], scleroderma [10], amyloidosis [11], Behçet's disease [12, 13], psoriasis [14], systemic sclerosis [15], Paget's disease, condyloma acuminatum [16], brown recluse spider envenomation [17], alcoholic cirrhosis [18], primary biliary cirrhosis [19], Sweet's syndrome [20], and low back pain [21, 22].

Despite being available since the 1950s, the FDA withdrew marketing approval for IV colchicine after numerous deaths were associated with its use were reported. In fact, 20 adult deaths were reported between 1983 and 2000 after IV administration of colchicine [23]. In addition, in 2007 a compounding error lead to 3 deaths in the US states of Washington and Oregon after patients received IV colchicine for back pain at an alternative medicine clinic [24, 25].

Biochemistry and Pharmacokinetics

Colchicine has a complex structure (Fig. 1). Tropolones have a hydrogen ion, which resonates between an oxygen and methyl group. Wallace [26] identified five colchicine analogues. It was found that one analogue lacked a tropolone structure; that particular analogue failed to have antiinflammatory activity (Table 1).

Fig. 1 Chemical structure of colchicine

Table 1 Colchicine pharmacokinetics [27]

Time to peak concentration	0.5–3 h
Bioavailability	25–50%
Protein binding	10–50%
Volume of distribution	2–12 L/kg
Mean elimination half-life	4.4–16 h therapeutic use 11–32 h in overdose
Hepatic metabolism	CYP 3A4
Lowest reported lethal dose	7 mg
High fatality rate	>0.5 mg/kg

The kinetics of colchicine are variably reported, but the most frequently cited observations regarding absorption from the gastrointestinal tract show the occurrence of a peak plasma concentration in 30 min to 3 h. Approximately 10–50% of the drug is protein bound, and its volume of distribution is estimated to be 2–12 L/kg. This information allows for an understanding of the limited efficacy of hemodialysis as a means of enhancing drug clearance. The major route of elimination of colchicine is through hepatic metabolism and biliary excretion. Colchicine undergoes extensive first-pass metabolism, which explains its decreased bioavailability of 25–50%. It is believed that enterohepatic recirculation may prolong exposure of the intestinal mucosa to colchicine [1]. Twenty percent of unchanged drug is excreted in the urine [28]. In the setting of preexisting renal or hepatic impairment, these elimination percentages may change. Thus, patients with impaired hepatic or renal

function are at significant risk for toxicity even on conventional dosing.

Colchicine has been reported to have a half-life of 4.4 to 16 h with therapeutic dosing and can reach 11–32 h in overdose. Colchicine has been found in white blood cells and in urine 9 days after a single intravenous bolus [7, 29, 30]. Because colchicine is metabolized through cytochrome P-450 CYP3A4, its breakdown may be inhibited or induced. Inhibitors of CYP3A4, such as clarithromycin, cimetidine, ketoconazole, erythromycin, diltiazem, ritonavir, verapamil ER, and grapefruit juice, frequently produce increases in serum concentrations of colchicine. Inducers of CYP3A4 include rifampin, St. John’s wort, phenobarbital, and phenytoin, which tend to lower serum colchicine concentrations. Multiple studies have demonstrated that drugs which inhibit P-glycoprotein, such as clarithromycin and cyclosporine, increase the risk of toxicity by increasing colchicine concentrations [31]. The combination of colchicine and statin medications has become a concern as numerous anecdotal reports have described cases of acute myopathy including rhabdomyolysis [32–35]. In 2010, the AGREE (The Acute Gout Flare Receiving Colchicine Evaluation) study concluded “low-dose colchicine yielded both maximum plasma concentration and early gout flare efficacy comparable with that of high-dose colchicine, with a safety profile indistinguishable from that of placebo.” This conclusion has led to recommendations for using low-dose colchicine for the treatment of gout. The use of low-dose colchicine decreases gastrointestinal side effects and should also reduce potential drug–drug interactions (Table 2) [36].

Pathophysiology

Microtubules are formed by polymerization of protein subunits, G actin and tubulin. Tubulin is present in α , β , and γ forms; α and β tubulin combine as dimers that serve as the building blocks of microtubules, and γ tubulin seems to play a role in the organization of these dimers during the assembly of a tubulin sheet. The sheet connects end to end to form the cylindrical origin

Table 2 Drug interactions [37, 38]

3A4 inhibitors	P-glycoprotein, substrates, and modulators
Macrolides: clarithromycin, erythromycin, telithromycin	Macrolides: erythromycin, clarithromycin
Antibiotics: ciprofloxacin, isoniazid	Cyclosporine
Cimetidine	Tacrolimus
Antifungals: fluconazole, itraconazole, ketoconazole	Verapamil
Calcium channel blockers: diltiazem, verapamil, nifedipine, mibefradil	Statins
Ritonavir, indinavir, nelfinavir, saquinavir	Fexofenadine
Grapefruit juice	Fenofibrate
Antidepressants: fluoxetine, sertraline, nefazodone	Antineoplastics
Protease inhibitors	TCAs
Amiodarone	Digoxin
Cyclosporine	HIV-1 inhibitors
	Glucocorticosteroids
	Ketoconazole

of the microtubule [39]. The microtubule is composed of repeating α and β tubulin subunits in a helical array measuring 24 nm in diameter (Fig. 2) [40]. The tubulin dimer has oppositely charged ends. Because the dimers are aligned repetitively, the microtubule they form has a positive end and a negative end. This alignment confers polarity to microtubules, which is crucial to their function. They are connected in elaborate networks depending on the function they serve within the cell. Microtubules form a diverse array of permanent (stable) and transient (unstable) structures. Stable microtubules are found when long-lived microtubules are needed, such as the axoneme in the flagellum of sperm and the marginal band of microtubules in most red blood cells and platelets or nerve cells. Unstable microtubules are found when cell structures composed of microtubules need to disassemble and assemble quickly. During mitosis, the cytosolic microtubule network that occurs in interphase disappears, and the tubulin from it is used to form the spindle-shaped apparatus that partitions chromosomes equally into daughter cells. Neurons must maintain long axons and do this with the aid of microtubules that continue to assemble (polymerize), and add to the chain. Disassembly of these stable structures has catastrophic effects, such as nonmobile sperm,

Fig. 2 Microtubule assembly occurs at the positive end, whereas disassembly occurs at the negative end. Antitubulin compounds prevent the addition of tubulin at the positive end and stop assembly

nonpliable red blood cells, and retracting axons [39].

Vinca alkaloids, colchicines, and podophyllin all inhibit the construction of microtubules that compose spindles in metaphase. This inhibition interrupts migration of the chromosomes toward the poles during mitosis but does not affect chromosome condensation. Because of this ability, colchicine is used in research to produce metaphase chromosomes for cytogenetic study. Each dimer of tubulin has a single high-affinity binding site for colchicine. When one or two vinca alkaloid-bound, podophyllin-bound, or colchicine-bound tubulin dimers attach to the end of the developing microtubule, additional assembly stops. Although these compounds inhibit spindle formation, they do not cause their disassembly at lower doses. When assembly is halted at the positive end of the microtubule, naturally occurring disassembly at the negative end continues. At high doses, however, some of these compounds also may enhance disassembly [41].

Microtubule formation is regulated by the number of tubulin dimers. As the number of “free” dimers within the cell increases, they bind to ribosomes and shut down the production of tubulin mRNA. The antitubulin compounds, via their inhibition of tubulin dimer polymerization, increase the number available to inhibit mRNA production. They do not seem to affect the more permanent microtubules because at therapeutic doses their impact is primarily on the *assembly* of the microtubule.

Vincristine and vinblastine also inhibit the formation of mitotic spindles, interrupting cell division. They appear to crystallize free tubulin dimers. As a result of this action, they preferentially kill rapidly dividing cells, such as tumor cells. This effect also causes cell death in gut and hair cells because of their rapid division. Although the vinca alkaloids bind to tubulin, preventing polymerization in a fashion similar to that of colchicine and podophyllotoxin, they seem to have a different binding site [40].

The mechanisms of action of colchicine have been studied extensively but remain unclear. Colchicine's action seems to depend on its rings, which are believed to bind microtubules, inhibiting the movement of intracellular granules. This inhibition disturbs the excretion of various components to the cell exterior. Colchicine inhibits multiple aspects of neutrophil activity, including adhesiveness, ameboid activity, mobilization, and degranulation of lysosomes, but the most studied is the inhibition chemotaxis [28]. Colchicine is thought to work primarily through this inhibited chemotactic mechanism in the treatment of gout (Table 3) [42, 43].

Clinical Presentation

Cases of overdose of colchicine are not common but are associated with significant morbidity and mortality. Mortality overall is approximately 10% but approaches 100% for cases in which the ingestion is 0.8 mg/kg or greater [2]. A review

Table 3 Stages of colchicine toxicity

Stage	Onset (postingestion)	Clinical findings
1. Gastrointestinal stage	0–24 h	Nausea, vomiting, diarrhea Abdominal pain Dehydration leukocytosis
2. Multi-organ failure stage	1–7 days	ARDS Cardiac arrhythmias, CHF Cardiac arrest Encephalopathy Cerebral edema Seizures Renal failure Hepatic failure DIC Bone marrow suppression Pancytopenia Hemolysis Metabolic derangements: metabolic acidosis Hypokalemia, hyponatremia, hypocalcemia Hypoglycemia (or hyperglycemia) Hypophosphatemia Myopathy Neuropathy Secondary sepsis
3. Recovery stage	7–21 days	Alopecia Recovery of organ function Rebound leukocytosis

Modified from [27].

by Baum and Meyerowitz found that although about 90% of persons treated with colchicine for gout are men, the intentional use of this drug in overdose occurs more often in women [44].

Acute ingestion of colchicine is heralded by gastrointestinal symptoms for the first 24 h. Profound nausea, vomiting, and diarrhea are common [29]. Abdominal cramping and melanotic stools are reported in several cases [3, 45, 46]. These symptoms can cause circulatory collapse due to fluid losses and electrolyte abnormalities. Gastrointestinal symptoms are used as an end point of

therapy in the treatment of gout. Typically, these symptoms ensue within minutes of ingestion. The cause is believed to be a direct toxic effect of colchicine on the gut epithelial cells [1]. Emesis may be centrally mediated as well, however, as suggested by an animal study by Ferguson [47] in which gastrectomized animals vomited anyway.

Beginning at 24–36 h, the second stage consists of multiple organ failure. Hematopoietic changes begin with noticeable peripheral leukocytosis [1, 16, 30], which reverses quickly and is followed by pancytopenia. Hemorrhage may develop secondary to hepatic dysfunction and thrombocytopenia. Hepatotoxicity and adult respiratory distress syndrome are described in multiple cases. Death during this stage is often secondary to hemodynamic collapse and arrhythmias. Disseminated intravascular coagulation is frequently reported [3, 29, 30, 46, 48]. Systemic abnormalities may include pancytopenia, coagulopathy, hepatic transaminase elevation, acidemia, renal insufficiency, and electrolyte abnormalities, such as hypophosphatemia, hypomagnesemia, hypocalcemia, and hypokalemia. Serum creatine phosphokinase or urine myoglobin concentrations initially should be monitored serially. Septic workup, including blood cultures, is indicated for unexplained fever. Chest radiographs may show interstitial lung changes. Colchicine plasma concentration may confirm the presence of the drug but in many cases does not correlate with the patient's condition [16]. Without preexisting colchicine levels, interpretation of these values is limited. Hepatic and renal dysfunction may prolong drug metabolism and elimination [30].

Bradycardia and irregular rhythms have been seen with intravenous colchicine administration. Hemodynamic profiles of cardiac failure in acute ingestions have been described in several case reports [2]. Cardiac profiles obtained by Sauder and coworkers [49] in a study of eight patients revealed that four patients had declining cardiac index and rising systemic vascular resistance; these patients subsequently died. Asystole has been reported within 24 h of ingestion. In one case, the ingestion of 0.4 mg/kg resulted in

Table 4 Clinical features of antitubulin agent overdose

	Colchicine	Vincristine	Vinblastine	Podophyllin	Etoposide/teniposide
Peripheral neuropathy	Reported	Common	Rare	Common	With vincristine

CNS central nervous system, IV intravenous, NR not reported

death. Eight of 12 deaths due to colchicine, according to poison center statistics from 1985 to 1997, indicated the cause of death to be cardiac [50].

Oliguric renal failure is a common problem in severe colchicine poisoning. One likely cause of renal dysfunction is the profound hypovolemia from sensible gastrointestinal fluid losses and accumulation of fluids that results from paralytic ileus and marked gastrointestinal tract edema [1, 3]. Volume depletion, combined with hypoxia and myoglobinuria secondary to colchicine-induced rhabdomyolysis, has resulted in azotemia, proteinuria, and hematuria [1, 29, 46].

Reported electrolyte abnormalities include hypokalemia, hyponatremia, hypocalcemia, and hypophosphatemia [30, 46, 49]. Hypocalcemia may be due to a direct effect of colchicine on bone resorption. Animal studies have shown that colchicine inhibits the rise of serum calcium after injection of parathyroid hormone [51].

Neurologic complications reflect central nervous system (CNS) and peripheral nervous system involvement. Mental status changes, including sedation, delirium, and coma, are the most common CNS manifestations. However, the incidence is very rare as colchicine does not cross the blood–brain barrier easily due to P-glycoprotein. Seizures also have been reported. Peripheral nervous system involvement includes myoneuropathy and axonopathy as consequences of chronic and acute overdose [52]. Ascending paralysis and loss of deep tendon reflexes

typically occur [53]. Myelin degeneration found on postmortem pathologic examination was thought to be the underlying peripheral manifestation in colchicine poisoning [1, 3].

Metabolic derangements also are well described in cases of colchicine intoxication. Lactic acidosis secondary to shock and tissue hypoxia is associated with colchicine toxicity; however, a more disruptive effect on cell metabolism also may contribute to the acid–base disturbance seen in many cases [30]. Rhabdomyolysis occurs fairly commonly in colchicine poisoning, manifested by myalgia, weakness, and marked elevation in serum creatine phosphokinase concentrations [27].

Alopecia marks the third stage of toxicity, which may be seen as early as day 6 and as late as day 14. Alopecia is due to the inhibition of mitotic activity in the hair follicles. Most commonly, alopecia begins on the scalp, then involves the axillae, trunk, extremities, and genital area. Regrowth generally occurs after several months, but failure of regrowth has been reported [54–56]. Rebound leukocytosis also occurs in phase III (Table 4).

Diagnosis

The diagnosis of colchicine toxicity is straightforward if a history of exposure is obtained. However, the signs and symptoms of colchicine toxicity could be easily mistaken for other

conditions without a known exposure. These conditions might include enterocolitis, sepsis, toxicity due to heavy metals (iron, arsenic, thallium, mercury), or chemotherapeutic agents. The typical toxidrome seen with colchicine poisoning would include gastroenteritis, hypotension, lactic acidosis, and prerenal azotemia [27].

Treatment

Intensive monitoring of vital physiologic parameters is imperative in a patient with colchicine intoxication. After initial resuscitative measures, attempts may be made to delay absorption. Activated charcoal (1 g/kg) can be administered (evidence level III). However, it is unknown if doing so alters the clinical course of colchicine overdoses. Colchicine undergoes enterohepatic recirculation; however, current evidence does not support the use of multi-dose-activated charcoal in the treatment of its toxicity [23]. Additionally, patients with colchicine toxicity may develop a paralytic ileus, which is a contraindication to this intervention. Hemodialysis has not proved to be beneficial for colchicine poisoning. Any patient with a suspected toxic ingestion of colchicine should be observed for symptoms or signs of toxicity for a minimum of 12 h. If signs of toxicity develop (see section on “[Clinical Presentation](#)”), intensive care unit admission is warranted.

Supportive care is the mainstay of treatment. Intravascular volume and blood product replacement may be necessary, especially if coagulation parameters are abnormal or bleeding is noted. Fluid requirements may be underestimated due to gastrointestinal loss. It is important to maintain renal clearance to enhance colchicine elimination. Ventilatory status should be monitored closely, with intubation and mechanical ventilation provided as indicated. Hemodynamic monitoring also should be performed in a critical care setting initially and on a continuing basis as needed. Vasopressor support and electrolyte replacement may be necessary. Urine output should be followed closely and adjustments made accordingly. As clinical toxicity progresses, patients should be watched for signs of infection, as they

become neutropenic and susceptible to opportunistic pathogens. Seizures should be treated with benzodiazepines or barbiturates (Grade III recommendation), and the possibility of underlying acidosis, hypoxia, or electrolyte abnormalities should be considered and corrected aggressively (Grade III recommendation) [3].

Injections of granulocyte colony-stimulating factor (G-CSF) have been used in several cases to treat bone marrow suppression (Grade III recommendation). Dramatic increases have been reported in some but not all cases [29, 57, 58].

The development of colchicine-specific Fab fragment antibodies is a promising therapy but remains unavailable commercially. These antibodies bind to colchicine and restore tubulin activity in vitro [59]. Studies performed in mice, using thermoregulation as an end point, showed a significant improvement in the group that received colchicine-specific IgG [60]. Anticolchicine antibodies were used successfully in a 25-year-old woman who presented 24 h after ingesting 60 mg (0.96 mg/kg) of colchicine, phenobarbital, and opium extract. She was hemodynamically unstable and required vasopressor support. Colchicine-specific Fab fragments derived from goats were administered intravenously 40 h after the ingestion. The patient's blood pressure began to increase 30 min after Fab administration. During the 6-h infusion of the maintenance dose of Fab fragments, fluid replacement continued, and urine output improved [61].

Some authors have advocated for considering early initiation of either whole blood or plasma exchange in patients presenting with lethal-dose colchicine intoxication. However, more research needs to be done investigating these therapies [62].

Indications for ICU Admission in Colchicine

Any patient with clinical signs of poisoning or confirmed ingested toxic dose.

Special Populations

Colchicine must be used cautiously in elderly patients owing to their increased risk of underlying

hepatic or renal dysfunction [26]. Patients with impaired hepatic or renal function have reduced colchicine clearance. Pediatric patients may be administered colchicine during therapy for conditions such as familial Mediterranean fever [8, 63], acne vulgaris [64], renal amyloidosis [65], or pericarditis [66], to mention only a partial list. There are reports of colchicine toxicity involving children, the first case appearing in the English literature in 2000. Unfortunately, fatal poisoning has occurred in the pediatric population [62, 67–69].

Pregnancy

Colchicine is classified as FDA pregnancy category C, meaning that the benefits may exceed the risks. However, well-controlled studies with colchicine in pregnant women have not been conducted. Colchicine has been shown to cross the placenta.

Key Points in Colchicine Overdose

- Narrow therapeutic index.
- Be aware of interactions between colchicine and CYP3A4 and P-glycoprotein inhibitors.
- Toxicological emergency requiring admission for any known or suspected overdose.
- Toxicodrome includes gastroenteritis, hypotension, lactic acidosis, and prerenal azotemia.
- Cornerstone of treatment is supportive care.

Vinca Alkaloids

The vinca alkaloids are derived from the Madagascar periwinkle (*Catharanthus roseus*), a perennial evergreen herb found in most warm regions of the world. Native to Madagascar, it has been naturalized in most tropical countries including the southern part of the United States. Interest in *C. roseus* among Western researchers began in 1949, when they studied its use in a tea made by Jamaicans for the treatment of diabetes mellitus. Although its use as a hypoglycemic agent did not evolve as a result of this investigation, bone marrow suppression was observed. Many alkaloids eventually were extracted from the plant, including vincristine, vinblastine, vindesine, and vinorelbine. Semisynthetic vinca alkaloids are also in use or under development. Although structurally similar (Fig. 3), these compounds vary in their clinical effects and application in the treatment of neoplastic diseases. The mechanism of action of these compounds is similar to that of colchicine and podophyllin, although with different binding sites on the tubulin dimer. Vincristine is used in combination therapy to treat solid tumors, lymphoma, and leukemia. Vinblastine is used in combination to treat bladder and breast cancers as well as Hodgkin's disease. Vinorelbine has been used for treatment of small cell lung cancer. Recommended doses for vincristine are shown below:

Fig. 3 Chemical structures of vincristine and vinblastine

Vincristine recommended dose for pediatric patients: 1.5–2 mg/m².
Vincristine recommended dose for adults: 1.4 mg/m².
A 50% reduction in the dose is recommended for patients with direct serum bilirubin concentrations exceeding 3 mg/dL [70].

Pharmacokinetics

The vinca alkaloids commonly are injected intravenously and seem to follow a three-compartment model (see Fig. 3). When ingested, vinca alkaloids’ absorption is unpredictable, although vinorelbine is frequently administered orally. When administered intravenously, vincristine rapidly distributes into tissue of the ileum, skeletal muscle, and kidney. It penetrates the blood–brain barrier poorly. Metabolism of these compounds is primarily hepatic. They are excreted in the bile, and less than 1% of vincristine and vinblastine are excreted in the urine. Renal elimination accounts for 18% of vinorelbine excretion.

Pharmacokinetics of Vinca Alkaloids

Compound	Renal elimination (%)	Elimination half-life (hr)
Vincristine ^a	<1	24
Vinblastine	<1	24
Vinorelbine	>18	27.7–43.6

^aClearance after IV administration: [71]

Adults: 189 mL/min/m²

Children: 482 mL/min/m²

Vincristine, and probably all the vinca alkaloids, inhibit the CYP3A subfamily. Troleandomycin, ketoconazole, nifedipine, erythromycin, cyclosporine, and vindesine all seem to increase serum concentrations of the vinca alkaloids. Calcium channel blockers, such as verapamil, seem to decrease protein binding of the vinca alkaloids, increasing the risk of neurotoxicity [72].

Pathophysiology

The nervous system is the primary target organ of vincristine toxicity. Vincristine disrupts the

normal process of microtubule formation, interfering with axoplasmic transport, which accounts for the prevalence of neural injury associated with its administration [73, 74]. At therapeutic doses of vincristine of 1.5 mg/m² (0.06 mg/kg), the onset of peripheral neuropathies may begin within 2 weeks and occurs with a nearly 100% incidence [75].

Vinblastine and vinorelbine seem to depolymerize microtubules at the negative terminus while stabilizing the positive terminus [41]. They cause less inhibition of microtubular polymerization and are less neurotoxic than vincristine. Their primary toxicity is bone marrow, which is often the dose-limiting factor during therapy with either drug.

Clinical Presentation

Acute Toxicity

Vincristine. Paresthesias usually begin in the hands, followed by sensory loss in the feet. Loss of ankle-jerk reflex occurs soon thereafter [76]. Although the sensory loss may progress, it seldom results in more proximal stocking-glove distribution deficits. Motor symptoms follow, with weakness of the extensors of the hands and feet being most pronounced. Nerve conduction studies may show slowing of nerve conduction velocity with decreased amplitude. Electromyography may rarely show signs of denervation in distal muscle. Morphological changes include demyelination with “die-back” pattern of axonal loss and dorsal root ganglion damage [77]. Cranial neuropathies are rare; however, ototoxicity with sudden transient hearing loss has been reported [78]. Sensory and motor symptoms usually abate within a few weeks of discontinuation of therapy, although mild distal sensory loss and absence of ankle-jerk reflexes may persist.

Although CNS penetration at therapeutic doses is relatively low, encephalopathy and seizures have been reported [79, 80]. In rare cases, they are the presenting sign of intravenous overdose and frequently occur a few days to a week after exposure. Initial signs and symptoms of overdose may include bone or muscle pain, abdominal pain, bleeding, or marrow depression [81–83]. Other

adverse effects of vincristine use include autonomic dysfunction, mucositis, paralytic ileus, bladder atony, fever, bone marrow suppression, alopecia, and hypertension [75, 83]. Trinkle and Wu [84] reviewed 18 cases of intravenous vincristine overdose in children (average age 10 years). There were four fatalities with a dose range of 0.2–0.6 mg/kg. The major lethal risk factors were hemorrhage due to thrombocytopenia and neutropenia-related infection. Paresthesias and loss of deep tendon reflexes occurred as early as 24 h. Nausea, vomiting, diarrhea, and abdominal pain usually occurred within 48 h. Paralytic ileus occurred in 66% of patients within a mean of 5 days. Thrombocytopenia and leukocytopenia occurred in most cases [84]. Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has been a relatively frequent occurrence after vincristine overdose [81, 83, 85].

Accidental intrathecal injection accounts for a large portion of the fatalities, and survival from such exposures is rare regardless of therapy [86]. (See “[Intrathecal Exposure](#)” below.) These therapeutic mishaps usually involve vincristine administration by personnel unfamiliar with the drug or confusion with other antineoplastic drugs that may be administered via that route. Dermal extravasation of vinca alkaloids has been associated with tissue loss [87]. (See “[Extravasation](#)” below.)

Vinblastine and Vinorelbine. These vinca alkaloids are less potent inhibitors of microtubular polymerization and are less neurotoxic than vincristine. Their primary toxicity is bone marrow suppression, which often is the dose-limiting factor during therapy with either drug and is the most common toxic effect of these drugs (see Table 1). Granulocytopenia occurs frequently. There are relatively few reports of overdose [88–91]. After overdose, onset of fever and diarrhea has been reported within a few hours. Pulmonary edema developed in one reported case at day 4 [91]. Vinorelbine also has been associated with bronchospasm and respiratory failure, but concurrent disease may have played a significant role [92].

Chronic Adverse Effects

Myocardial ischemia has been reported after therapeutic doses of the vinca alkaloids [93–96];

however, this patient population tends to be at greater age-related cardiovascular risk. Delayed (24 h) onset of epithelial keratopathy was reported after ocular exposure to vinblastine solution; it resolved over 2 weeks without treatment. Ototoxicity also has been reported (with vincristine and vinblastine). Tinnitus occurred in a 29-year-old man within hours of treatment with vinblastine, doxorubicin, bleomycin, and dacarbazine and lasted 7–10 days after each of multiple treatments; mild sensorineural hearing loss persisted in the high-decibel range [97]. Pancreatitis has been reported after therapeutic doses of vinorelbine [98, 99]. As these cases show, predicting the toxicity of the vinca alkaloids frequently is confounded by coexistent disease and the presence of other chemotherapeutic agents. Similar to vincristine, vinblastine and vinorelbine also have been associated with SIADH [100, 101]. Hepatotoxicity including veno-occlusive disease has been reported particularly in pediatric patients during combination therapy with vincristine (see section “[Special Populations](#)”).

Treatment

Intravenous Exposure

Supportive measures are the mainstay of care. Peripheral neuropathies usually resolve or improve on withdrawal of the drug. Seizures usually respond to benzodiazepines or barbiturates or both (Grade III recommendation). Phenytoin would not be expected to be efficacious (see ► [Chap. 20, “Toxicant-Induced Seizures”](#)). Additionally, a theoretical concern with the use of phenytoin is that it seems to potentiate the effects of vincristine and vinblastine by interfering with tubulin polymerization [102]. SIADH is managed most appropriately by fluid restriction. Vincristine has a large volume of distribution due to tissue uptake and is highly protein bound. Hemodialysis is of little benefit with regard to enhancement of drug clearance. Plasmapheresis has been performed with a favorable outcome [103], but data supporting its use are inadequate. Folinic acid has been used in humans [104] and studied in animals [105], but its efficacy is controversial. If

used, a suggested dosing schedule is “100 mg IV every 3 h for 24 h and then every 6 h for at least 48 h” [70]. Finally, glutamate also has been studied as a preventive intervention against neurotoxicity. In patients receiving therapeutic doses, neurotoxicity seemed to be reduced [106]. This particular intervention, too, is based on limited data.

Indications for ICU Admission in Vinca Alkaloid Overdose

1. The maximum tolerated doses of these drugs are not established. Patients who have received excessive amounts should be admitted for observation on a cardiac monitor.
2. The length of observation after intravenous overdose with one of the vinca alkaloids should be 3–4 days because the onset of symptoms may involve that degree of delay. This is dose dependent, with high-dose exposures reportedly causing onset of symptoms within only a few hours [81, 83].

Intrathecal Exposure

With few exceptions [107, 108], the accidental intrathecal or intraventricular injection of vincristine has resulted in death [86, 109, 110]. Autopsy results have shown evidence of an ascending chemical leptomeningitis; ventriculitis; and necrosis of the spinal cord, brainstem, and cerebellum [111, 112]. Folinic acid [110, 111, 113, 114] and glutamic acid [114, 115] have been administered in many of these cases despite the relative paucity of supporting data and in response to the devastating and typically lethal nature of this injury. CNS washout involves removal of cerebrospinal fluid and replacement by Ringer’s lactate. Ferayan et al. [116] reported significant motor and sensory impairment in a 7-year-old patient who ultimately survived. They employed a technique first described by Dyke [115]. During a routine admission for chemotherapy, 0.5 mg of vincristine accidentally was injected intrathecally. The error was recognized before the injection was complete, and 75 mL of cerebrospinal fluid was

withdrawn immediately thereafter. That volume was replaced with Ringer’s lactate via an additional lumbar puncture. In less than 2 h, a catheter was placed in the right lateral ventricle by way of a burr hole; 1 L of Ringer’s lactate was infused through the ventricular catheter at a rate of 100 mL/h. Afterward, 15 mL of fresh frozen plasma was mixed with each liter of Ringer’s lactate, and the rate was reduced to 55 mL/h. That infusion was continued for 24 h with the effluent passing through the lumbar catheter. Glutamic acid (250 mg every 8 h) was administered via nasogastric tube, and then continued orally for 1 month. The patient became symptomatic 7 days postexposure with urinary retention and sensorimotor impairment of the lower extremities. There was significant residual impairment at follow-up 34 months after exposure [116]. Aggressive replacement and lavage washout is not always successful [86, 110], but at present it seems to be the only viable therapy (Grade III recommendation).

Extravasation

Extravasation typically causes pain, swelling, and erythema within minutes. While blister formation may occur over the subsequent days, skin ulceration usually does not occur [117]. Subcutaneous injection of 250 U of hyaluronidase in 6 mL of normal saline circumferentially at the site has been recommended; this should be followed by the application of heat for 1 h in the event of extravasation of vincristine or vinblastine. This procedure should be repeated four times daily for 3–5 days. Boman et al. (1996) demonstrated significant reduction of dermal toxicity when vincristine was administered in liposomes [118].

Special Populations

Children are the most common victims of accidental overdose or intrathecal injection. This is usually due to lack of familiarity with the drug or confusing it with another agent. It is imperative that stringent protocols for identification and administration of these compounds be

followed because toxicological treatment, particularly after intrathecal administration, is of limited efficacy.

- Hepatic veno-occlusive disease has been reported in several pediatric and some adult patients [119]. Bisogno et al. studied 41 patients with veno-occlusive disease and found a higher percentage of patients in children less than 1 year of age. Risk factors appear to be young age and concomitant radiotherapy [120].
- Renal Failure: Vinblastine 14%, vincristine 12%, and vinorelbine 18% are eliminated in the urine. This is primarily the parent drug and a smaller amount of the metabolite.
- Vincristine can induce severe peripheral neuropathy in patients with Charcot–Marie–Tooth syndrome. Vindesine has been successfully used as a substitute [121].
- Vinblastine, vincristine, and vinorelbine are rated FDA Category D (risks may exceed benefit) for pregnancy and breast-feeding. Human data are limited but animal studies suggest high risk [122–124].
- Patients taking drugs that inhibit CYP3A sub-families such as itraconazole and ketoconazole are at increased risk of developing toxic concentrations (Grade III recommendation) (see Table 2) [113, 114, 125].
- Occupational Exposures: Some studies have raised concerns regarding potential occupational exposures to vinca alkaloid in veterinary and human health-care workers. However, serious adverse health effects outside of allergic reactions have yet to be demonstrated [126–129].

Key Points in Vinca Alkaloid Overdose

1. Fatal exposures are almost always the result of iatrogenic administration.
2. People inexperienced with the use of these compounds should work under close direct supervision of medical professionals with substantial training and experience in the use of these compounds.
3. Therapeutic errors have been avoided by the institution of strict protocols for identification and administration of these drugs.

4. Administration via mini-bags may reduce intrathecal injection [130]

Podophyllin and Podophyllin Derivatives

Podophyllotoxin (Fig. 4) is found in the rhizome and roots of *Podophyllum peltatum*, also known as *mandrake* or *May apple*. Native Americans used podophyllotoxin as an emetic, and the Chinese used it (*gui jiu*) as an abortifacient, as treatment for snakebites, and as an aid to purging intestinal parasites [131–133]. Podophyllin was included in the United States Pharmacopeia in 1820 [134]. Purification and isolation of podophyllotoxin was first accomplished in 1880 [132, 133]. Podophyllotoxin resin, or podophyllin, was used widely in the United States as a cathartic and an ingredient in proprietary medicines (e.g., Carter’s Little Liver Pills) and topically in a 20–25% solution for condylomata until such uses were associated with reports of serious toxicity [135–144].

Herbal remedies erroneously may contain podophyllin because *mandrake* also is used to refer to *Mandragora officinarum*, which has anticholinergic properties [145]. Poisoning also has been reported with herbal remedies obtained in countries outside the United States [146–149].

In 1942, podophyllin was reported to treat venereal warts successfully, and in 1947 podophyllin-induced mitotic arrest was shown, leading to the investigation of its use for cancer treatment [132, 134]. In response to the high toxicity and low water solubility of purified podophyllin, chemical modification of the compound was carried out, and many of the resulting compounds were studied. In the 1960s, synthesis and biologic testing of the podophyllin derivatives teniposide and etoposide were initiated. Currently, prescription ointment containing 0.5% podophyllin (Podofilox[®], Condyllox[®]) (US brand names are given in examples. These may vary depending upon the country.) and physician-applied 25% podophyllin solution (Podocon –25[®]) are used for the treatment of anogenital warts [150, 151]. Podophyllin also is used topically to treat oral hairy leukoplakia [152]. Etoposide (VePesid,

Fig. 4 Podophyllin and derivatives

Etopophos) and teniposide (Vumon) are used in chemotherapy regimens for cancers, including testicular cancer, small cell lung cancer, lymphoma, and acute lymphoblastic leukemia [40, 132, 134, 153–155].

Pharmacokinetics of Podophyllin and Podophyllin Derivatives

Podophyllin [143, 156, 157] Available in topical preparation from 0.5% to 25% in alcohol or benzoin tincture

Highly lipid soluble

Well absorbed across friable tissue

Dermal application of 0.1–1.5 mL of 0.5% topical preparation led to peak serum concentrations of 1–17 ng/mL 1–2 h after application with an elimination half-life of 1–4.5 h

Oral and intravenous pharmacokinetic data unavailable

Etoposide [150, 155, 158] Oral formulation with polyethylene glycol, citrate, and glycerin

Intravenous formulation with polyethylene glycol, polysorbate 80, and 30% ethanol

Poor water solubility

Renal elimination (significant in children, 55% recovery in urine at 24 h)

Oral bioavailability of 50%

No significant first-pass effect

97% protein bound

Volume of distribution highly variable between 7 and 17 L/m²

Terminal half-life 3–11 h after intravenous infusion

Teniposide

Intravenous formulation with ethanol, which is reconstituted before infusion

Greater than 99% protein bound

Volume of distribution highly variable between 3 and 44 L/m²

Half-life variable between 6 and 48 h, depending on the model

Biliary excretion 10% of elimination

Some central nervous system penetration

Pathophysiology

The cell cycle consists of four phases: *G*₁ (growth), *S* (DNA duplication), *G*₂ (preparation for cell division), and *M* (mitosis – cell division). Interphase consists of all phases except mitosis [159]. Although the spindle poisons, such as colchicine, podophyllin, and the vinca alkaloids, act in mitosis (specifically, causing metaphase arrest),

podophyllin derivatives (etoposide and teniposide) act in interphase and prevent mitosis.

Podophyllin, similar to colchicine, binds reversibly to tubulin at the colchicine-binding site, resulting in mitotic arrest [40, 131]. Microscopically, this activity results in metaphase arrest with clumped chromosomes because the mitotic spindle is unable to form without microtubules [132]. Disruption of microtubules also causes decreased cellular transport. Podophyllotoxin also inhibits the incorporation of labeled thymidine and uridine into cells by inhibiting nucleoside transport [160]. Neurotoxicity is thought to be related to microtubule binding and inhibition of axoplasmic flow [161].

Podophyllotoxin derivatives have a mechanism of action distinct from that of the parent compound. Etoposide does not inhibit microtubule assembly compared with podophyllin [160, 161]. Cells treated with etoposide, teniposide, and similar derivatives were found to have a low mitotic index, indicating that cells were inhibited from entering mitosis [162]. Time analyses indicated that the cells likely arrest in late S or early G₂ phase [162, 163]. Later analyses showed that these derivatives may bind to tubulin, but this effect is seen at much higher and clinically impractical doses [132].

Radiolabeled nucleoside (thymidine) incorporation into DNA is inhibited with etoposide and teniposide [162, 164]. This mechanism of action is shared with podophyllin. Inhibition of cell proliferation is not linked to this mechanism, however [162, 165].

In 1974, DNA fragmentation by etoposide and teniposide was reported and represented a breakthrough in the understanding of the mechanism of action of podophyllin derivatives [160]. Podophyllin itself has no effect on DNA. Structure–activity studies indicated that derivatives with a hydroxyl group at the C-4' position are required for this activity [160, 166]. DNA breakage was found to correlate well with the cytotoxic effects of the drugs [167]. Subsequently, podophyllin derivative–induced DNA fragmentation has been correlated with inhibition of topoisomerase type II, which is essential for uncoiling of DNA before replication [168]. Topoisomerase

II inhibition is now believed to represent the primary mechanism of action of these drugs, and they are classified today as topoisomerase interactive agents along with anthracyclines, such as doxorubicin [132, 134, 155]. Current research is ongoing regarding the antitumor potential of novel podophyllin derivatives, some of which have reached clinical trials [169–172].

Clinical Presentation

During therapeutic administration of etoposide and teniposide, the most significant dose-limiting effect is bone marrow suppression (seen in 90% of patients), with granulocyte nadirs occurring in 7–14 days and platelet nadirs occurring in 9–16 days after administration. Marrow recovery usually occurs within 20 days [134, 153, 158, 173]. Nausea, vomiting, anorexia, and diarrhea are reported but are milder when caused by other chemotherapeutic agents [134]. At high doses, mucositis may be dose limiting. Anaphylaxis may occur. CNS depression and hypotension have been reported during intravenous infusion (see Table 1). Transient elevations in liver function tests have been reported. In children with acute lymphocytic leukemia, treatment has been associated with the development of secondary leukemias [174, 175]. Hemolysis and renal failure have been reported in conjunction with teniposide-related antibody [176]. CNS depression, hypotension, and metabolic acidosis have been reported in children treated with teniposide; however, they also had clinically significant ethanol concentrations due to the high ethanol concentration in the infusion [177]. Neurologic manifestations, such as peripheral neuropathy, are less common after administration of the topoisomerase II inhibitors than with the spindle poisons, but they have been reported as well, often in high-dose use and in conjunction with drugs such as vincristine [178, 179]. Neurologic signs and symptoms, such as somnolence and seizures, have been reported after high-dose etoposide therapy for malignant glioma [180]. One case report of inadvertent supratherapeutic use of oral etoposide for 25 days detailed a reduction in T

lymphocytes and blastic transformation that persisted at 57 months along with relapse-free remission [181]. Etoposide treatment induces other malignancies such as acute myelocytic leukemia and myelodysplastic syndrome [182].

Podophyllin is far more toxic than its derivatives and has clinical effects similar to those of colchicine. Fatality has been reported after ingestion of 350 mg [183], and survival has been reported after ingestion of 2.8 g [98]. Toxicity has occurred from ingestion [136, 140, 144, 149, 153, 183–187], cutaneous absorption [132, 141, 143, 161, 188, 189], subcutaneous injection [190], and intramuscular injection [191]. Cases of toxicity from cutaneous absorption typically involved prolonged contact, large surface areas, or friable mucosa. Death has been reported after cutaneous application [185, 192].

The hallmarks of toxicity include nausea, vomiting, altered mental status progressing to coma, rapidly progressive peripheral neuropathy with paresis and areflexia, and delayed myelosuppression. These effects have been reported to be delayed 10 h after ingestion [136] and 20 h after topical application [188]. Review of the case reports indicates, however, that the patients initially developed gastrointestinal symptoms (one was given Syrup of Ipecac) and alteration in mental status (one also was ethanol intoxicated), followed by delayed and profound CNS depression and coma. Several reports of toxicity after cutaneous exposure detailed vomiting 12–13 h post application followed by a coma within 30 h of application [141, 189]. Other reports included early gastrointestinal symptoms followed by delayed (24 h) coma. Some patients may present primarily with peripheral neurologic symptoms, such as neuropathy and paresthesia [137, 146, 147, 191, 193]. Patients may recover fully from coma, which may last 10 days [135, 138, 141, 143, 188]. Electroencephalogram may show diffuse slowing, with cerebrospinal fluid findings typically normal but, at times, showing elevated protein [138, 194]. Fever, seizure activity, and visual/auditory hallucinations also have been reported.

Patients often present with tachycardia and tachypnea. Hypotension has been reported. In fatal cases, renal failure and circulatory collapse

may occur [144, 187, 189, 192]. Status epilepticus occurred shortly after ingestion in a pediatric case [186]. Noncardiogenic pulmonary edema and idioventricular bradycardia have been reported in a fatal case [192]. Necrotizing myopathy has been reported in a patient who died 9 weeks after podophyllin ingestion owing to sepsis [187].

Survivors may have neurologic sequelae, such as persistent peripheral neuropathy lasting months to several years, that may manifest after the initial encephalopathy has resolved [184, 195]. Some patients have developed persistent lower extremity paralysis and encephalopathy and radiologic findings of cerebral atrophy [149, 186, 196]. Dorsal radiculopathy, manifesting as profound loss of position sense, is reported [184]. Podophyllin has been proposed as an experimental model for deafferentation [146]. Absence of alopecia is notable in that it clinically differentiates podophyllin from acute colchicine or vinca alkaloid toxicity.

Diagnosis

Initially, leukocytosis may be seen ($55,000/\text{mm}^3$) [143]. Granulocytopenia and thrombocytopenia are delayed by 5 days and typically resolve over 2–3 weeks. Peripheral leukocytes may show enlarged nuclei with dense chromatin granules and cytoplasmic and nuclear vacuolization [136]. Bone marrow examination may reveal evidence of mitotic arrest [142, 143, 188] and vacuolization of erythroblasts and plasma cells [157]. Lactic acidosis has been described in a fatal case in a patient who had concomitant alcoholic cirrhosis [136]. Hypocalcemia has been reported [140], along with elevated serum hepatic transaminase and uric acid concentrations.

Autopsy findings include mitotic arrest in granulocytes and intestinal mucosal cells; diffuse petechial hemorrhages; pulmonary, renal, and hepatic congestion; and cerebral edema [136, 144, 189]. The bone marrow is hypocellular with cytoplasmic vacuolization of myeloid precursors [197].

Abnormalities on computed tomography or magnetic resonance imaging show cerebral atrophy in some survivors [149, 196]. Some patients have developed persistent lower extremity

paralysis; nerve biopsy specimens may reveal axonal degeneration and loss of large myelinated fibers, with gradual regeneration as recovery occurs [110, 112, 149].

Because of its prominent early gastrointestinal effects, toxicity with podophyllin and derivatives may be confused with gastrointestinal disorders. In addition, podophyllin use may not be reported to the treating physician if it is applied as an ointment or applied by the patient's physician in the office. The common presentation of fever, lethargy, and leukocytosis mimics CNS infection. The presentation of hypotension, altered mental status, and fever mimics septic shock. Podophyllin toxicity may present with ascending paralysis and loss of reflexes similar to Guillain-Barré syndrome. Delayed bone marrow suppression leads to thrombocytopenia, granulocytopenia, and anemia, which may cause the treating physician to suspect other causes of bone marrow suppression, such as infection or malignancy.

Treatment

Gastrointestinal decontamination with activated charcoal may be beneficial after an acute suicidal podophyllin ingestion if given within the first hour postingestion. However, it is not known if this intervention alters the clinical course or outcome. Decontamination of skin should be performed if topical preparation has been applied. The mainstay of treatment is supportive care, including prevention of infection and screening for delayed bone marrow suppression. Blood products should be used if needed. Hemoperfusion has been used for podophyllin toxicity with variable results [136, 142, 143, 149, 185, 188, 192]. Because of the high lipid solubility, volume of distribution, and degree of protein binding (97–99%) of podophyllin and its derivatives, hemodialysis is not likely to be useful.

Indications for ICU Admission in Podophyllin or Podophyllin Derivatives Poisoning

1. Because of delayed and profound central nervous system effects, observation in an

ICU setting for at least 24 h should be considered for any patient with a significant exposure to podophyllin or podophyllin derivatives, particularly patients with evidence of altered mental status and rapidly progressive neuropathy.

2. Hemodynamic instability, seizures, or respiratory distress.

Although G-CSF has been used with some success to treat colchicine-induced neutropenia, its use has not been reported in podophyllin poisoning. G-CSF has been used in combination chemotherapy, including etoposide, for the prevention and treatment of hematopoietic toxicity and to facilitate more intensive chemotherapy regimens [198–203]. There is no specific antidotal therapy for podophyllin toxicity or that of its derivatives, etoposide and teniposide.

Key Points in Podophyllin Toxicity

1. Podophyllin poisoning is typically reported after ingestion or large surface dermal application to friable mucosa.
2. Severe symptoms can be delayed up to 20 h, particularly after dermal application.
3. Treatment is primarily supportive.

Special Populations

Pregnant Patients

These drugs are not intended for use in pregnancy. Podophyllin has been used to induce abortion. Reports link podophyllin to intrauterine fetal demise and birth defects [137, 204, 205].

Oncology Patients

In addition to increased risks of infection associated with immunosuppression and bone marrow suppression, after single-agent administration, concomitant cytotoxic medication use may lead to a synergistic increase in neurologic and hematologic toxicity.

This chapter addresses drugs that have the basic phenethylamine structure with various substitutions (Fig. 1). Amphetamine and methamphetamine, substituted amphetamines (3,4-methylenedioxymethamphetamine [MDMA; “Ecstasy”] and related compounds), related anorexigens, and new psychoactive substances (novel drugs of abuse) are discussed.

Plant-derived stimulants structurally related to amphetamine have been used by local populations for thousands of years. Ephedrine from *Ephedra* (*ma huang*) has been used in China for more than 5000 years, and cathine and cathinone from *Catha edulis* have been used in East Africa for more than 600 years. Both of these plants, and their isolated active ingredients, continue to be used today as medications, drugs of abuse, and in social rituals.

Although amphetamine was first synthesized more than 100 years ago, the first investigations of its pharmacologic properties and potential clinical use began in the 1920s. In 1932, Smith, Kline, and French introduced an over-the-counter nasal inhaler containing *d/l*-amphetamine under the trade name Benzedrine[®] marketed for congestion. This preparation was easily abused for the central nervous system (CNS) stimulant properties. Each Benzedrine[®] inhaler contained a folded paper impregnated with 250 mg of amphetamine base along with other aromatic compounds. This paper was removed and portions of it were swallowed or soaked in beverages, then ingested [1]. Benzedrine[®] abuse by American students, musicians, truck drivers, and prisoners became problematic, and the clinical and social difficulties now classically associated with amphetamines were detailed in reports published in the 1930s and 1940s. In 1949, the Benzedrine[®] inhaler was renamed Benzedrex[®] and reformulated to contain propylhexedrine, a potent vasoconstrictor with approximately 8% of the CNS stimulant activity of amphetamine. Abuse of propylhexedrine was soon reported, however, and continues to occur sporadically [2].

Early claims of amphetamine’s efficacy against fatigue and tiredness were reported in the lay press and the medical literature, and by the 1940s, amphetamines were widely prescribed for various indications, including barbiturate overdose, shock, coma, smooth muscle spasm of the

genitourinary or gastrointestinal tract, chronic encephalitis, postural hypotension, and “problem children and enuresis”[1–3]. During World War II, amphetamine use was widespread among the combatants and domestic workforces in the USA [4]. Legitimate prescribing of amphetamine in the 1960s and 1970s reflected its use as an anorexiatic, but vast amounts were diverted for illicit use. In 1969, the legal production of amphetamine was between 80,000 and 100,000 kg, enough for fifty 10-mg tablets per each person in America [4]. Federal regulation of prescribing patterns and restrictions on approved indications for amphetamines led to a decrease in the quantity manufactured by pharmaceutical companies. As legitimate manufacture declined, illicit amphetamine and methamphetamine production took its place. Clandestine synthesis and manufacture is now a major problem throughout many parts of the world.

The true prevalence of amphetamine and related drug use and resultant medical complications are difficult to gauge, but it is clear that use is widespread. Data from the 2013 US National Household Survey of Drug Abuse demonstrate that 595,000 people used within the past month [5]. The 2014 Annual Report of the American Association of Poison Control Center’s (AAPCC) National Poison Data System reveals 22,753 cases of exposure to amphetamines and related compounds, hallucinogenic amphetamines, or methamphetamines.

In that report, 10 deaths were attributed to toxicity from amphetamines and related compounds, 48 were attributed to toxicity from methamphetamine, and 12 were associated with hallucinogenic amphetamines [6]. Figures from the US Drug Abuse Warning Network Emergency Department (ED) data indicate that methamphetamine-related ED visits are surging again, with 102,961 visits reported in 2011, after decreasing from 132,576 visits in 2004 to 64,119 in 2009 [7]. While methamphetamine use, abuse, and toxicity was primarily a concern in the western USA, use is now nationwide. Amphetamine and amphetamine derivative use and toxicity are a worldwide phenomenon [8]. Global Methamphetamine seizures increased 158% between 2008 and 2013 [9].

Seizures of “amphetamine-type stimulants” peaked in 2011 and have remained high. These

Fig. 1 Chemical structures of phenethylamines: 1, phenethylamine; 2, phenylpropanolamine; 3, ephedrine; 4, pseudoephedrine; 5, mescaline; 6, cathinone; 7, methcathinone; 8, amphetamine; 9, 4-bromo-2,5-dimethoxyphenethylamine; 10, 4-methyl-2,5-dimethoxyphenethylamine (2-CD); 11, methamphetamine; 12, 2,5-dimethoxy-4-bromophenylisopropylamine (DOB); 13, 2,5-dimethoxy-4-methylphenylisopropylamine (DOM); 14, 3,4-methylenedioxyamphetamine (MDA); 15, 3,4-methylenedioxymethamphetamine (MDMA); 16, 3,4-methylenedioxyethamphetamine; 17, phentermine; 18, fenfluramine; 19, aminorex; 20, phenmetrazine

increases are largely driven by increased global methamphetamine use. Sale in Asia and South-East Asia has increased with trafficking through distribution centers in West Africa and transport through Southern Africa and Europe, suggesting worldwide networks. Use has also increased throughout North America and Europe. In 2011, 9,500 seizures of methamphetamine were reported by 22 European countries, led by Turkey, Norway, Lithuania, Sweden, and Latvia. Of note, seizures in the Czech Republic and Germany increased significantly since 2008 [10]. Worldwide “Ecstasy” use is much lower and appears to be decreasing in North America, Europe, and Australia, though use increased in Oceania, and East and South-East Asia between 2008 and 2014 [9].

Available forms of amphetamines include pharmaceutical preparations and clandestinely synthesized formulations. Pharmaceutical preparations include amphetamine, methamphetamine, methylphenidate, and lisdexamfetamine (see also Fig. 1). These preparations generally are approved only for short-term weight loss, narcolepsy, and attention-deficit disorder; however, they are used clinically for a variety of conditions, including depression, Tourette syndrome, closed head injury, pain, stroke, and depression. Additionally, they are used for psychiatric conditions, including mania, schizophrenia, and obsessive-compulsive disorder. Available forms include tablets, capsules, sustained-release forms, and elixirs. Concentration of active ingredients varies, and impurities, adulterants, and by-products of synthesis may contribute to toxicity. Amphetamine and methamphetamine are often called “speed” and “crank” (Table 1) and may be snorted, injected, or ingested. A crystalline form of methamphetamine, known as “ice,” is purified by recrystallization. This form has a relatively low melting point, allowing it to be volatilized and inhaled. Crystal methamphetamine abuse first was reported in Asia in the early 1980s [11]. Concerns that this might produce epidemic problems of a magnitude similar to that of problems that occurred with cocaine have been largely unfounded.

The term “*designer drug*” originated in the United States in the early 1980s to describe compounds manufactured by street chemists that resemble various legal and illicit parent chemicals

Table 1 Common street names of amphetamine derivatives

Amphetamine
amp, browns, hearts, fives, tens, white cross, beans, bam, black beauties, speed, bennies, cranks, crystal, dexies, greenies, lidpoppers, pep pills, pink and green amps, sparkle plenty’s, uppers, whites
Methamphetamine
bambita, crystal, meth, speed, crank, ice, glass, shabu, peanut butter crank
3,4-Methylenedioxyamphetamine
XTC, Ecstasy, Adam, X, E, Molly, clarity, essence
4-Bromo-2,5-dimethoxyphenethylamine
CBr, bromomescaline, nexus, Venus, N, Eve, synergy, 2C-B
3,4-Methylenedioxyamphetamine
love drug

Note: Street names are region specific and often overlap. The actual content of illicit drugs may be a function of drug substitutions, by-products of synthesis, and adulterating agents

with minor structural modifications [12]. Current terminology labels these chemicals “synthetics” or “hallucinogenic amphetamines.” Contrary to popular belief, most hallucinogenic amphetamines are not novel compounds developed by street chemists; rather, they are compounds that were studied in the past by researchers and pharmaceutical companies. The description of the synthetic process and pharmacologic activity of these compounds (numbering in the hundreds) is easily accessible in the scientific literature and the popular press [13]. Many of these substances were never formally tested for safety, efficacy, or adverse effects and their pharmacokinetics and pharmacodynamics may be poorly characterized, if studied at all. The manufacture of these substances often occurs in conditions that are unsanitary, chemical reactions may be performed poorly, and inappropriate substitutions for unavailable reagents may occur.

3,4-Methylenedioxyamphetamine is the prototypical hallucinogenic amphetamine. It was originally patented by Merck in 1914 and studies were performed evaluating its use in psychotherapy, though it did not prove safe and effective. 3,4-Methylenedioxyamphetamine is a stimulant and entactogen, inducing euphoria and increased sensory awareness [14]. In the 1980s,

it was marketed as “Ecstasy” and “E,” and illicit use increased significantly [15]. The popular press noted the worldwide phenomenon of MDMA use, especially at “rave parties,” large dance gatherings with electronic music [16]. 3,4-Methylenedioxy-methamphetamine and related compounds are usually taken orally and are available as tablets, capsules, crystals, or powder; in recent years use of crystalline and powder MDMA by nasal insufflation (“snorting”) is increasing. Significant variability in MDMA content in tablets is reported, ranging from 1 to 225 mg per tablet [14]. Contamination is high, with only 79% of tablets found in one study to contain pure MDMA, while the remainder included chemicals such as paramethoxyamphetamine (PMA), ketamine, lidocaine, ephedrine, caffeine, and others [14]. Use of “Molly,” short for “molecule,” began in the 2000s. Molly was initially sold as a powder, though tablets are also common. It is marketed to users as pure MDMA and potentially used due to the perception of greater safety as the adverse effects of Ecstasy are attributed to contaminants. Confusion arises as Molly has also come to refer to several other synthetic drugs.

The emergence of new psychoactive substances (often referred to as “bath salts” in the USA and “legal highs” in Europe) including synthetic cathinones and other hallucinogenic amphetamines occurred in the late 2000s. Along with synthetic cannabinoid receptor agonists, the use of synthetic cathinones increased significantly and received significant media attention. Calls to US poison centers about “bath salts” started in 2009. Mephedrone, methylenedioxypyrovalerone, methylone, and various product names were first mentioned in the AAPCC’s annual report in 2010 as an emerging public health threat when there were 5,624 exposures [17]. The trend increased with 24 reported deaths in 2011 [18]. Given the numerous chemicals and product names (with unknown chemical composition), it is difficult to accurately track exposures. The annual reports of the AAPCC start to group all synthetic stimulants together and refer to them as hallucinogenic amphetamines, with 12 attributed deaths in 2014 [6]. Interestingly, the use of synthetic cathinones seemed to decrease over the

subsequent years in the USA, in conjunction with media reports of psychosis and violent behavior. The most recent annual report attempts to name the presumed agent in fatality reports noting two deaths due to 2,5-dimethoxy-4-ethylphenethylamine and two to uncategorized amphetamine (hallucinogenic) [19]. This trend is in stark contrast to the experience in Europe where seizures of synthetic cathinones reported to the EU Early Warning System have increased to greater than 10,000 between 2011 and 2013. Additionally, from 2008 through 2014 there have been growing numbers of new synthetic cathinones identified each year [20]. England and Wales report nine deaths due to these agents in 2007, but 60 in 2013 [9]. Analysis and characterization of these chemicals is enhanced by programs such as Sweden’s STRIDA project, which has reported sympathomimetic toxicity and death due to confirmed cases of 3-methylmethcathinone [21]. In Australia, the number of seizures of these chemicals peaked at 132 in 2011–2012, but have been on the increase again with 92 reported in 2013–2014 [22].

Chemicals such as PMA and paramethoxy-methamphetamine (PMMA) gained attention as contaminants of Ecstasy that are often associated with fatalities. Originally described in Australia in the 1980s, PMA causes fatal hyperthermia, dysrhythmias, and intracranial hemorrhage [23]. PMMA causes similar signs and is also associated with fatalities earning it the street names “Death” and “Dr. Death” for both [24].

Illicit drug development has continued with the emergence of the “2C” class of chemicals known for very high potency. Originally developed by Dr. Alexander Shulgin and described in his book, *PIHKAL (Phenylethylamines I Have Known and Loved)*, the 2Cs are phenethylamines with methoxy groups at the 2 and 5 positions on the phenyl ring and a halogen or lipophilic group at the 4 position. The 2Cs are highly serotonergic due to the presence of the methoxy groups, but can be used as the basis to synthesize a strong stimulant with the addition of a 2-methoxybenzyl group to the nitrogen of the phenethylamine’s amino group. These are now marketed as research chemicals or “herbal LSD” and sold via the

Internet. They are distributed on blotter papers due to the microgram doses that are required for clinical effect and cause seizures, hallucinations, muscle rigidity, and rhabdomyolysis [25].

Local, state, and federal legislatures struggle to control synthetic drugs. Each molecular modification made to a banned substance results in a slightly different chemical, which may not be scheduled by authorities, allowing producers and abusers to avoid criminal prosecution. The US Controlled Substances Analogue Enforcement Act of 1986 largely attempted to close this loophole, but controversy in court regarding what precisely is meant by “analog” has hindered prosecution. In the lawsuit captioned *United States v. Damon S. Forbes*, a federal district court in Colorado dismissed the prosecution’s case because the law is too vague [26]. More recently, in *McFadden v. United States*, the US Supreme Court upheld a lower court’s conviction of a distributor of bath salts after he marketed them with wording borrowed from the analog act, including “not for human consumption” and noting that the product did not contain any controlled substances or analogs, though he did compare them to cocaine and methamphetamine [27]. The legal status of these chemicals varies significantly between nations. While several countries have utilized existing consumer or medication safety legislation to curtail distribution of new chemicals, Ireland, Austria, Portugal, and Romania have passed laws specifically aimed at preventing the distribution of at new agents and in Sweden police were granted the authority to confiscate and destroy harmful substances [28]. The synthesis of many of these compounds is relatively uncomplicated and inexpensive, however, and the lure of potentially large profits and the continued popularity of many of these substances make the hallucinogenic amphetamine phenomenon unlikely to be short-lived.

Chemistry and Pharmacology of Amphetamines and Derivatives

The word *amphetamine* is an abbreviation for *alpha-methylphenethylamine* [29]. The class of CNS stimulant drugs to which amphetamine

belongs is called the phenethylamines. The basic structure of this group of drugs is an aromatic ring (*phen* for phenyl) attached to a two-carbon chain (*ethyl*) bearing a basic nitrogen at the distal end of the carbon chain (*amine*) (see Fig. 1). Although primarily regarded as CNS stimulants, substitution of the fundamental phenethylamine nucleus can result in effects including sedation, stimulation, and hallucinations [29]. The large number of phenethylamine derivatives that have been synthesized allows detailed study of the structure-activity relationships of this series of compounds [29, 30]. Based on these structure-activity relationship investigations, some general inferences can be made about the pharmacologic effects of a given phenethylamine derivative based on its chemical structure as this has significant effects on which neurotransmitter is principally affected. There are essentially four sites on the phenethylamine on which substitution would affect the overall pharmacology of the compound: the amino group, the α and β carbons of the ethyl chain, and the aromatic ring.

Substitution of the amino nitrogen with a single methyl group increases central activity, as is seen when comparing methamphetamine with amphetamine [31]. Conversely, amphetamine causes more pronounced peripheral actions than methamphetamine. Mono-*N*-substituents larger than methyl groups cause a decrease in excitatory properties with retention of anorexiant effects. This observation has been exploited in the development of antiobesity agents that have reduced the potential for abuse relative to the amphetamines [31, 32]. Di-substitution of the nitrogen to form a tertiary amine significantly reduces activity, frequently to the point of abolition [31].

Substitution of the α carbon (to the nitrogen) with lower alkyl groups causes the CNS stimulant and anorexiant effects. The lack of significant CNS effects in compounds without substitutions at the α -position (e.g., β -phenethylamine) apparently is due to their facile degradation by monoamine oxidase (MAO) into compounds that do not penetrate the CNS. Compounds with an alkyl α -substituent (e.g., amphetamine) are poor substrates for MAO, have good oral bioavailability, and readily penetrate the CNS [32]. The branching at the α -carbon induces a chiral center. With respect to the absolute

Fig. 2 Metabolic transformations of prescription medications to both isomers of methamphetamine

configuration of amphetamine, two isomers exist (*dextro* [*d*] and *levo* [*l*]). The pharmacologic profiles of these two compounds are distinct. The alerting activity of the *levo* (R)-isomer is only about one tenth that of the *dextro* (S)-isomer and about half the strength as a psychotomimetic [33]. This stereospecificity also is apparent with methamphetamine [31]. The *l*-isomer of methamphetamine (present in Vicks[®] Inhalers as *l*-desoxyephedrine) has greater peripheral sympathomimetic and less CNS stimulant activity than the *d*-isomer. The *l*-isomer is also formed as a metabolite of the anti-Parkinson's drug selegiline (Fig. 2) [34]. The greater CNS stimulation induced by *d*-methamphetamine makes it the preferred agent not only as an illicit stimulant but also as a therapeutically useful antiobesity agent. The *d*-isomer of

methamphetamine is a metabolite of the antiobesity agent benzphetamine [35]. The European over-the-counter analgesic/antipyretic famprofazone is metabolized to the *d*-isomer and *l*-isomer of methamphetamine, although the *l*-isomer predominates (see Fig. 2) [36].

Several compounds oxidized at the β -carbon (e.g., cathinone, ephedrine, and pseudoephedrine) retain CNS activity. Hydroxylation at this position lowers potency. Substitution with a keto, phenyl, or hydroxyl group at the β -carbon results in about 50%, 18%, and 4%, respectively, the stimulant activity of phenylisopropylamine. This decreased potency is due largely to the diminished ability of the hydroxylated compound to cross the blood-brain barrier [31]. Phenylpropanolamine has only about 1% of the ability to cross the

blood–brain barrier as its nonhydroxylated congener, amphetamine [33].

Substitution of the phenyl ring, particularly with alkoxy moieties, diminishes central sympathetic activity and increases hallucinogenic effects [32]. Exceptions to these generalizations are common, e.g., PMA and PMMA both retain sympathomimetic properties. Significant serotonergic effects are also produced by these same substitutions and clinical effects ranging from altered perceptions to hallucinations are noted. Hydroxylation of the aromatic ring also leads to diminished central activity presumably due to decreased blood–brain barrier penetration. Halogenation of the phenyl ring reduces sympathomimetic effects, but serotonergic effects can be enhanced [32]. These structural variations are shown in Fig. 1.

Pharmacokinetics of Amphetamine and Methamphetamine

time. Motorcycle gangs were the primary manufacturers and sellers of methamphetamine throughout California in the 1970s. Over time, drug trafficking organizations operating between the United States and Mexico began to produce, distribute, and sell substantial quantities of methamphetamine throughout the United States [37]. Worldwide, Asia has seen significant growth in methamphetamine manufacture. Reports suggest major production of tablets occurs in Myanmar that are then smuggled into China and Thailand [9]. Although a wide variety of synthetic approaches are possible for the preparation of methamphetamine, only a handful are used with any regularity for illicit production of the drug. Other derivatives, such as MDMA, 3,4-methylenedioxymphetamine, and 2,5-dimethoxy-4-bromoamphetamine, tend to be more difficult to prepare and are produced less commonly. Methamphetamine street chemists or “cooks” learn synthetic procedures by word-of-mouth, apprenticeship with another cook, in jail, books, the Internet, and, occasionally, the primary chemical literature. Poor training, technique, and facilities, combined with generalized chemical ignorance and misinformation, can lead to relatively poor yields of methamphetamine, heavily contaminated product, and production of potentially toxic synthetic by-products.

Historically, illicit preparation of methamphetamine centered on derivatization of phenyl-2-propanone (P2P); typically, this involved condensation of the P2P with methyl amine to form the imine (Schiff base) followed by reduction to form the amine (methamphetamine) (scheme I in Fig. 3). The P2P method is not a stereospecific synthesis (i.e., it produces a 50:50 *d:l* mixture). Although popular for many years, use of methods involving P2P has declined substantially since the 1990s. The impetus for this decline is multifactorial. In the United States, P2P is now a Drug Enforcement Administration schedule II compound (restricted), and the detection of a “P2P lab” is easy because P2P has a pungent odor, likened to cat urine. The process is also time consuming and requires special materials [37]. Finally, the process evolved when ephedrine and pseudoephedrine, starting materials for

Illicit Synthesis of Methamphetamine

The illicit synthesis of methamphetamine is not difficult and requires little or no formal education in synthetic chemistry. Manufacturing sites evolved from small labs to “superlabs” capable of manufacturing pounds of methamphetamine at a

Scheme I

Scheme II

Fig. 3 Methods of illicit preparation of methamphetamine

alternative reductive dehydroxylation methods, were readily available.

The reductive removal of the benzylic (β) hydroxy group of ephedrine or pseudoephedrine has become the preferred illicit synthetic approach to methamphetamine. One of the most common methods of reductive methamphetamine production from ephedrine or pseudoephedrine employs red phosphorus and hydriodic acid (scheme II in Fig. 3). In efforts to avoid detection, cooks often obtain the necessary chemicals from veiled sources. Red phosphorus is extracted from matchbook strikers or road flares, and hydriodic acid is produced in situ by mixing mineral acids with iodine crystals used for water purification.

Another common method employed by clandestine chemists for reductive dehydroxylation of ephedrine or pseudoephedrine involves the use of an alkali metal, such as lithium or sodium, in the presence of liquid ammonia (scheme II in Fig. 3).

This method of illicit methamphetamine production often is referred to as the "Nazi" method, though it is technically known as the "Birch reduction." The metals typically are obtained from batteries, and the ammonia is obtained from agrochemical sources. Reduction of either *l*-ephedrine or *d*-pseudoephedrine via the red phosphorus/hydriodic acid or the "Nazi" method yields only *d*-methamphetamine, another reason cooks tend to favor these methods and starting materials.

Likely due to simple processes and easily available precursors, small labs began to produce significant amounts of methamphetamine causing problems in the communities where they were located. Clandestine methamphetamine laboratories may be the source of toxic exposures to the general public, fire fighters, and other first responders [38]. Mineral acids cause serious burns, and metal/ammonia reduction has

associated inhalational and dermal burn hazards due to residual ammonia or metal hydroxide left after production. Red phosphorus does not share the propensity to induce catastrophic liver damage possessed by yellow phosphorus (This is discussed in detail in ► Chap. 84, “Phosphorous”). Residual unreacted sodium or lithium metals or hydride-reducing agents present an explosive or corrosive hazard if they come in contact with atmospheric moisture or decontamination water. Additional concerns associated with clandestine methamphetamine synthesis are exposure to a variety of organic solvents, such as diethyl ether, acetone, and dichloromethane, and burns and blast injuries from chemical explosions.

Many synthetic by-products are formed because of impure starting materials, primitive facilities, and chemical ignorance [39, 40]. These by-products can be structurally diverse and may be present in highly variable amounts in a given mixture of methamphetamine. They may also contribute to the toxicity of a given batch of illicit methamphetamine, but few studies have examined this possibility. A notable example is the lead poisoning of IV methamphetamine users in Oregon in 1988 when there were 37 suspected and 14 confirmed cases [41].

By 2004 several US states had enacted laws to reduce the availability of pseudoephedrine with federal law passed in 2005. A short period of decreased methamphetamine exposure was noted, but production shifted outside of the United States, where it remains, managed mainly by Mexican trafficking organizations. More recently, there has been a resurgence of smaller labs domestically producing very small batches of methamphetamine using equipment like a 2 l bottle in a process known as “shake and bake,” which is generally the Nazi method on a very small and mobile scale [37].

Pathophysiology of Phenylethylamine Effects

Although the data are complex and sometimes conflicting, most suggest that amphetamines cause clinical effects indirectly, by increasing the

synaptic concentration of biogenic amines (dopamine, norepinephrine, serotonin) through increased release from presynaptic nerve terminals and decreased reuptake from the synapse [42]. The degree to which any of these neurotransmitters is affected depends on the structure of the particular amphetamine derivative. Some evidence indicates that amphetamine may act directly on catecholamine receptors, but this is believed to be a minor mechanism [43]. The effects of amphetamine on neurotransmitter systems are studied most extensively on dopaminergic neurons, which provide a model to explain amphetamine-induced biogenic amine effect. Normally the dopamine reuptake transporter system removes dopamine from the synapse. In the presence of amphetamines, the direction of this transport is reversed, resulting in movement of catecholamines out of the neuron [44]. The reuptake transporter system is sodium dependent, although evidence exists for sodium-independent transporters as well [45]. Amphetamines also cause release of intracellular dopamine in a manner that is independent of depolarization and calcium flux. Additionally, amphetamines enter the neuron by passive diffusion or exchange diffusion through the reuptake transporter, where amphetamine enters the cell concurrent with transport of dopamine out of the cell [46]. Amphetamine may also enhance internalization or phosphorylation of the dopamine transporter, inhibiting dopamine reuptake from the synapse [44]. Amphetamine decreases vesicular uptake of dopamine, increasing the cytoplasmic dopamine concentration. This decrease may be due to effects of amphetamine on vesicular monoamine transporter-2 or diffusion of amphetamine into the vesicles to change the pH preventing vesicular dopamine uptake [44]. The increased intracellular dopamine contributes to the pool available for release [47]. At high concentrations, amphetamines also have a weak inhibitory effect on MAO type A; however, this effect is unlikely at concentrations achieved by commonly used doses [48, 49].

At low doses, amphetamine increases central release of norepinephrine, which seems to induce appetite suppression and, in animal models, some forms of increased locomotor behavior.

Amphetamines reduce appetite and food intake in humans and many animal models [42, 50]. Higher doses are associated with an increased release of dopamine, which contributes to the anorexiant effect and results in stereotypical behaviors and other forms of increased locomotor activity in animal models [42, 51]. High doses of amphetamines or lower doses of serotonin-selective forms, such as MDMA, increase release of serotonin that may alter perceptions and, together with dopamine increase, may cause psychosis.

Amphetamine-induced psychosis and stereotypical behaviors are used as a model for schizophrenia in animals, and there are many similarities between these conditions in humans. Both conditions are thought to result from dopaminergic overactivity, and both respond to typical antidopaminergic antipsychotics. In animal models, increased amphetamine-induced dopaminergic activity in the nucleus accumbens results in an increase in general locomotor activity, whereas a dopamine increase in the striatum results in species-specific stereotypical behaviors, such as rearing, licking, and gnawing. These behaviors are dose dependent, with higher doses required to induce the more characteristic individual stereotypical behaviors [42]. These stereotypical behaviors are represented in humans as compulsive performance of repetitive tasks, such as assembling or disassembling mechanical objects, pacing, or foot tapping.

The hallucinogenic amphetamines, notably MDMA, and some pharmaceutically developed preparations, such as fenfluramine, have prominent serotonergic actions that account for some of their short- and long-term effects. Much of the research regarding these compounds focuses on MDMA. Because of MDMA's importance as a drug of abuse, it is discussed in detail. MDMA acts by several mechanisms (similar to the previous discussion of dopamine) to increase the concentration of serotonin in the synapse [52–54]. Animal models demonstrate that MDMA, when given at excessive doses, is associated with serotonergic neuronal injury, a reduction of activity of the serotonin synthetic enzyme tryptophan hydroxylase and decreased density of the serotonin uptake transporter [15]. The loss of

serotonergic axons, as shown by histopathologic studies, occurs in a variety of animal models [55, 56]. Primate studies document serotonin neuronal loss lasting 7 years, suggesting that these changes are permanent [57]. Some human data support these findings. Controlled studies in MDMA users documented decreased concentrations of 5-hydroxyindoleacetic acid in cerebrospinal fluid, altered neuroendocrine responses to serotonin agonists, and decreased serotonin transporter binding as shown by positron emission tomography [58–60]. These studies, when coupled with clinical investigations suggesting that MDMA users have impaired memory and cognitive performance and long-term psychiatric complaints, build a case for serotonergic neuronal toxicity, especially in cases of high doses or prolonged use [60–63]. All of these data are confounded, however, by the fact that the subjects studied also had exposure to multiple other drugs. Similar data suggest that methamphetamine may cause persistent neurochemical deficits in dopaminergic and serotonergic neurons [64].

Clinical Presentation and Life-Threatening Complications

Systemic Effects

Systemic toxicity after use of the amphetamines reflects a hyperadrenergic crisis that may be severe including hyperpyrexia, tachycardia, hypertension, and agitation. Rhabdomyolysis, hepatorenal failure, disseminated intravascular coagulation, dysrhythmias, cardiovascular collapse, and death may result [65, 66]. The relative contributions of norepinephrine and serotonin to the genesis of these clinical findings are unknown, and patients exhibit features of serotonin toxicity and the sympathomimetic toxidrome (see ► [Chaps. 24, “Serotonin Syndrome,”](#) and ► [25, “Sympathomimetic Syndrome”](#)). This clinical picture can occur with the traditional amphetamines and the substituted amphetamines and is reported both at therapeutic doses and in overdose [65–67]. The features of the clinical presentation of phenethylamine toxicity are summarized in Table 2.

Table 2 Clinical manifestations of phenethylamine toxicity

Cardiovascular	Neurological	Pulmonary	Gastrointestinal	Metabolic	Muscular	Skin
Hypertension Sinus tachycardia Ventricular tachydysrhythmias Vasculitis Valvulopathy Cardiomyopathy Myocardial ischemia/ Infarction Hypotension	Euphoria Agitation/ violent behavior Paranoia Hallucinations Seizures Coma Intracranial bleed/ infarction Venous sinus thrombosis Hyperreflexia Mydriasis Chorea	Pulmonary edema, and ARDS Pulmonary hypertension	Nausea Vomiting Hepatitis Diarrhea Gut ischemia	Acidosis Hyperpyrexia Hyponatremia: SIADH or dilutional	Bruxism Trismus Rhabdomyolysis	Flushing Diaphoresis Excoriations

SIADH syndrome of inappropriate antidiuretic hormone, *ARDS* Acute respiratory distress syndrome

Severe hyperthermia is associated with a poor clinical outcome. The precise mechanism of amphetamine-mediated temperature elevation is unknown. In animal models, hyperthermia was not attenuated by decapitation, but it was improved with curare, suggesting that temperature elevation was secondary to muscular heat generation [68, 69]. Other animal models suggest, however, that hyperthermia is centrally mediated and appears to be blunted by treatment with serotonin and dopamine antagonists [70]. Clinical reports describe cases of hyperthermia with and without excess agitation or muscular activity [71].

Central Nervous System Effects

The CNS is the principal site of action of the amphetamines, and consequently many of the clinical signs and symptoms of toxicity reflect CNS effects. Therapeutic use of amphetamines is usually accompanied by feelings of energy and well-being. Anorexia is a common and often desired effect. As toxicity progresses, agitation and unpredictable behavior become manifest. Animal studies note frequent stereotypical species-specific behaviors [42]. This behavior manifests in the clinical setting as repetitive tic-like movements or continued performance of certain tasks. Aggressive and paranoid behavior is common, and

injuries and death due to violent behavior and excessive risk taking are common [72]. Rodent studies show that aggressive behaviors and mortality are enhanced under crowded conditions [73, 74]. Large doses can result in seizures that may be due to direct drug effect or may be secondary to intracranial hemorrhage [75, 76].

Intracerebral hemorrhage is associated with amphetamine use irrespective of blood pressure [68]. Intraparenchymal and subarachnoid bleeding can occur, and patients with preexisting arteriovenous malformations may be at increased risk. Vasculitis is strongly associated with both oral and intravenous use of amphetamines. This small- and medium-vessel disease produces a beading pattern on radiologic imaging and can occur in the brain and other vascular beds [75, 76]. Ischemic strokes are also described.

Cardiovascular Effects

The acute cardiovascular effects of amphetamines largely reflect sympathomimetic effects. Lower doses are typically associated with sinus tachycardia, palpitations, and mild hypertension. Larger doses may produce supraventricular and ventricular dysrhythmias [77]. Hypertension may be severe and result in end-organ damage. Occasionally, isolated constriction of vascular beds results in

localized organ ischemia [78, 79]. In addition to vasospasm, necrotizing angitis of smaller vessels occurs, creating a beading pattern on radioangiography [75]. Myocardial ischemia, infarction, and global cardiomyopathy are reported, although these complications seem to be less frequent compared with cocaine use [80]. Fenfluramine, dexfenfluramine, and aminorex fumarate, anorexigenic agents that are no longer sold in most countries, were associated with pulmonary hypertension and valvulopathy [81].

Gastrointestinal Effects

Gastrointestinal effects of amphetamines probably reflect the ability of these drugs to compromise vascular supply, either through systemic hypoperfusion or through localized vasospasm. Ischemic gut is reported [79]. Many cases of hepatitis associated with amphetamine use are described, and these cases continue to accumulate with regard to the hallucinogenic amphetamines [82–84]. The mechanism of liver injury is not entirely clear; some cases are associated with hyperthermia, but other cases occur in patients with normal temperatures [83]. Data show hepatocytes exposed to methamphetamine suffer damage due to reactive oxygen species causing glutathione depletion, lipid peroxidation, and mitochondrial toxicity [85]. Currently, no antidotal therapy seems to be successful and supportive care is the mainstay of therapy. The role of liver transplantation in cases of amphetamine-induced liver failure is unclear, and success rates are low [83].

Dermatologic/Muscular Effects

Along with other stimulants, the amphetamines cause rhabdomyolysis [86]. The mechanism of muscle damage is unclear but may include agitation, extreme motor activity, seizures, hyperthermia, coingestion of other toxins (e.g., cocaine, tobacco, ethanol), or a combination of these factors [87]. Patients typically present with an elevation of creatine phosphokinase and have a positive urine dip-stick ortho-toluidine test for hemoglobin

and myoglobin [87]. Chronic amphetamine use is associated with alopecia, although the mechanism is unknown [88]. Self-inflicted excoriations can occur when compulsive or repetitive behaviors cause the patient to scratch repeatedly. Delusions of parasitosis (“crank bugs”) while rare may be accompanied by disfiguring attempts to remove the perceived insects or worms from the skin [89].

Pulmonary Effects

Amphetamines cause both cardiogenic pulmonary edema and the acute respiratory distress syndrome [80]. Pulmonary hypertension was well described with fenfluramine, dexfenfluramine, and aminorex fumarate use, but it is also associated, in a case report, with illicit amphetamines [90]. Asthma may be exacerbated. Any pulmonary complication associated with injection drug use (e.g., infection, granulomas) may also occur. Pneumothorax or pneumomediastinum result from barotrauma associated with inhalational drug use.

Genitourinary Effects

Urinary frequency and acute urinary retention are associated with MDMA [91]. Although renal dysfunction may occur in conjunction with amphetamine toxicity, it is believed to be secondary to rhabdomyolysis, volume depletion, vasculitis, hyperpyrexia, or a combination of secondary factors rather than direct drug toxicity.

Psychiatric Effects

Chronic high-dose use of amphetamines and their derivatives can result in amphetamine-induced psychosis [92]. Typically, users have paranoid ideation with ideas of reference [61, 62]. As the psychosis progresses, hallucinations may develop, and paranoid delusions may provoke sudden violent responses. Symptoms usually abate or disappear with abstinence, but recovery is often delayed and occasionally incomplete [62]. A variety of other psychiatric illnesses,

including depression, anxiety disorders, and panic attacks, are also associated with use of amphetamines [62, 77].

Oral Effects

Long-term use of methamphetamine is associated with characteristic dental pathology commonly known as “meth mouth.” Abusers have extensive dental caries. Potential explanations include poor oral hygiene, increased intake of food and beverages with high sugar content, and bruxism. There are contradictory data to implicate decreased saliva in this phenomenon [93].

Clinical Presentation and Life-Threatening Complications Associated with Various Designer Drugs

Toxicity of the hallucinogenic amphetamines largely reflects the sympathomimetic toxidrome that occurs with overdose of amphetamine and methamphetamine. The ring substitutions confer serotonergic activity that can produce specific clinical findings and toxicity. Data for some of the lesser used phenethylamines are sparse. There are considerable data, however, describing toxicity due to MDMA from case reports and series describing side effects and toxicity in the psychotherapeutic setting, pharmacokinetic and pharmacodynamic studies, or after recreational use. Capsules or tablets of MDMA average about 200 mg each, though they vary widely with a reported range of 66–465 mg [94].

Hayner and McKinney [95] divided adverse reactions to MDMA into three classes: (1) acute reactions with therapeutic doses, (2) overdose reactions, and (3) residual effects. Acute reactions at therapeutic doses commonly include tachycardia, tremor, tight jaw muscles, bruxism, nausea, headache, and sweating. Less commonly, extremity numbness and tingling, hallucinations, ataxia, blurry vision, and nystagmus are reported. Mydriasis, hyperreflexia, and gait instability may also occur. Ventricular dysrhythmias and cerebrovascular accidents are reported after allegedly

“therapeutic ingestions” of amphetamine and MDMA [65]. Users also report a variety of emotional and cognitive effects, including euphoria, increased energy, decreased appetite, positive changes in attitude or feelings, expanded mental perspective, and heightened sensual arousal [96]. Although MDMA often is referred to as the “love drug,” its effect on sexual function is often detrimental [97]. While most of MDMA’s psychological effects are described as positive and relate to the perception of improved insight and interpersonal communication, undesirable symptoms, such as anxiety, nervousness, and depression, can occur. Difficulty with cognition and judgment is noted in volunteers [98].

Toxicity from MDMA is manifested by sympathetic excess similar to amphetamine toxicity, including tachycardia, dysrhythmias, hypertension progressing to hypotension, hyperthermia, muscular rigidity, disseminated intravascular coagulation, rhabdomyolysis, and acute kidney injury [65, 95, 99]. Some patients with MDMA toxicity also have superimposed serotonin toxicity (see ► Chap. 24, “Serotonin Syndrome”) caused by the serotonergic effect of the drug. Because these drugs are metabolized in part by CYP2D6, genetic poor metabolizers or those individuals who take medications that inhibit this enzyme may be at increased risk [100–102]. MDMA toxicity is associated with raves, dance clubs, and electronic music festivals [65, 103, 104]. Vigorous dancing coupled with inadequate fluid intake may predispose MDMA users to hyperthermic crisis and collapse [65]. Recommendations to keep hydrated are occasionally taken to excess, however, and several cases of severe hyponatremia are reported in rave participants. Hyponatremia is attributed to MDMA-induced SIADH and combined with the intake of hypotonic fluids [100, 105–107]. Cases of acute hepatitis are reported after single doses and chronic use of MDMA [65, 82, 84]. Hepatitis usually resolves, but some cases have progressed to fulminant hepatic failure ending in death or requiring liver transplantation [82]. Aplastic anemia is also reported [108, 109]. MDMA modulates immune function in vitro, but the clinical correlates of this finding are uncertain [110].

The third category of reactions described by Hayner and McKinney are attributable to residual effects [95]. Mild residual reactions, such as exhaustion, fatigue, depression, nausea, numbness, and flashbacks, and more significant symptoms, such as anxiety attacks, persistent insomnia, rage reactions, and psychosis, are described. These residual symptoms persist for hours to 2 weeks. Others describe a variety of psychiatric effects, primarily panic disorders, psychosis, flashbacks, and depression that may be delayed in onset and may persist for months [61, 111, 112]. These cases seem to vary with respect to duration of symptoms and response to various psychotherapeutic agents, including haloperidol, amitriptyline, and fluoxetine. MDMA-induced disruption of serotonin homeostasis may be responsible for several psychiatric disorders after use due to the association between disordered serotonin and depression, psychosis, anxiety, panic, and eating disorders and data showing MDMA causes marked reduction of serotonergic neurons in primates [55]. Additionally, there is evidence that MDMA use is associated with subtle cognitive deficits [113].

Diagnosis of Toxicity from Phenethylamines

The diagnosis of phenethylamine use and toxicity should be based primarily on the recognition of the clinical features of sympathetic excess (see ► Chap. 25, “Sympathomimetic Syndrome”), hallucinations, and, in the case of ring-substituted derivatives such as MDMA, serotonin toxicity or serotonin syndrome (see ► Chap. 24, “Serotonin Syndrome”). Other conditions that result in the clinical findings of excess sympathetic tone, fever, or hallucinations should be considered. See Table 3 for a list of differential diagnoses. Some phenethylamines are associated with other toxicities that may not be secondary to this sympathetic excess, such as hepatotoxicity. Clinicians should be aware of these idiosyncratic toxicities as well.

Laboratory tests and radiographic studies serve primarily to identify medical or traumatic causes

that may account for the clinical condition of the patient or that may be present concurrently with phenethylamine use. During initial stabilization, a rapid blood glucose determination is indicated. In patients with altered mental status, tachycardia, and fever with unclear history, infectious processes should be suspected, and an appropriate search for a source should be conducted, including a chest radiograph, urinalysis, lumbar puncture, and blood cultures, as clinically indicated. This constellation of signs and symptoms may also reflect an intracerebral hemorrhage (unrelated or secondary to stimulant use), and a computed tomography scan of the head may be indicated. The complete blood count may show hemoconcentration from decreased fluid intake or increased insensible fluid losses. The white

blood cell count may be elevated with a leftward shift secondary to demargination from catecholamine excess. Electrolyte analysis may show hyponatremia, hypernatremia, or hyperkalemia. A metabolic acidosis may be present due to lactate-associated metabolic acidosis from hypoperfusion, or seizure activity. Respiratory alkalosis may occur as compensation for metabolic abnormalities, or it may occur primarily, as a result of anxiety or amphetamine stimulation of the respiratory center. In cases of significant toxicity, creatine kinase and troponin-I may be measured to assess rhabdomyolysis and cardiac ischemia. Urinalysis may show a positive dip-stick ortho-toluidine test indicating blood, free hemoglobin, or myoglobin. Liver function tests may be indicated if amphetamine-induced hepatitis is suspected.

If the diagnosis is unclear, measurement of serum salicylate, theophylline, and lithium concentrations is indicated because these substances may show a similar clinical picture in overdose. Thyrotoxicosis may also mimic amphetamine toxicity and can be assessed with a measurement of serum thyroid stimulating hormone and free serum thyroxine concentrations. Amphetamine use may cause elevation of serum thyroxine concentrations, which resolves when drug use is stopped [114]. Withdrawal from ethanol or sedative-hypnotic drugs may present a similar clinical picture that may be deduced from historical details.

Laboratory Analysis for Amphetamine Compounds

While it would be ideal to be able to obtain a quick, inexpensive qualitative determination of drugs of abuse, current methods of screening are not adequately specific to confirm the presence of amphetamine. The sensitivities and specificities of a urine drug screen in the presence of hallucinogenic amphetamines are unknown. The most common analytic technique for qualitative screening for amphetamine-like stimulants is the immunoassay. A variety of immunoassays have been developed to detect phenethylamines, including

radioimmunoassay, kinetic interaction of micro-particles in solution, cloned enzyme donor immunoassay, and enzyme-multiplied immunoassay technique, among others. Although there are differences among these techniques, they all employ an antibody designed to recognize the chemical structure of amphetamine. The specificity of the antibody depends on the uniqueness of the chemical structure of the analyte. In the case of compounds structurally unrelated to phenethylamines, such as cocaine, there are few substances that would interfere with the immunoassay and cause a false-positive result. As demonstrated above, a wide variety of compounds containing the basic phenethylamine nucleus exist, some of which are frequently prepared illicitly and abused (e.g., methamphetamine) and others that are available over the counter and used therapeutically (e.g., pseudoephedrine). The possibility of a false-positive immunoassay result for amphetamine from a structurally related compound is greatly increased. There is not a complete lack of specificity, however. Antibodies are designed specifically for interaction with amphetamine and methamphetamine. Although other compounds interact with the antibodies, it is typically only at drug concentrations greater than the concentration threshold required to give a positive result for amphetamine and methamphetamine. A positive result for an immunoassay is reported when a concentration greater than a predetermined cutoff value is detected. Concentrations less than this cutoff are considered negative because there exists a statistically significant chance that the result is due to an interfering compound. One of the more commonly used immunoassays in the USA is the EMIT-II monoclonal amphetamine/methamphetamine assay (Beckman Coulter®, Brea, California). The US Substance Abuse and Mental Health Services Administration set a cutoff concentration of 1000 ng/mL in urine as a positive *d*-amphetamine and *d*-methamphetamine for federal workers [115]. The EMIT-II package insert reports the concentrations of a series of other phenethylamine compounds that produce a positive result approximately equal to that of the 1000 ng/mL cutoff calibrator (Table 4) [116]. A few nonstimulant compounds do not possess the

classic phenethylamine skeleton but may give a false-positive result for a phenethylamine immunoassay screen. The exact reasons for these interactions are not clear. Immunoassay tests exist for MDMA, but their use on a urine drug screen panel is hospital or clinic dependent. MDMA may be detected by methamphetamine immunoassay, but at a significantly higher concentration than is required for the MDMA test. The new psychoactive substances are not detectable on the standard amphetamine, methamphetamine, or MDMA immunoassays, likely due to their major structural differences from these chemicals [117]. Testing for these chemicals is possible with gas chromatography and mass spectrometry, though this requires additional cost and time. Given the lack of specificity, the clinical utility of the urine amphetamine immunoassay is unclear. Patients should be treated for amphetamine toxicity empirically based on their clinical presentations, laboratory results, and low risk for other emergent pathology unrelated to drug toxicity.

Forensic cases involving employment disputes or criminal prosecution may require confirmation of a positive immunoassay result. Confirmation is typically performed using gas chromatography with mass spectrometric detection. This method allows definitive structural identification and quantitation of the analyte and is mandatory in child custody cases and other legal situations where there is no room for false positive immunoassay results. The lack of correlation between blood or urine concentrations of phenethylamine stimulants and clinical response makes such confirmation in clinical cases typically unnecessary.

Clinical and forensic interpretation of concentrations of methamphetamine in blood is an area fraught with difficulty. They are expensive and usually require the capabilities of a commercial laboratory, delaying results for days from when the sample is obtained. There does not seem to be a consistent link between measured concentration and degree of intoxication or impairment. Similarly, deaths have been attributed to methamphetamine intoxication at concentrations well below those found in individuals who have survived without deficit [118]. Any detectable concentration of methamphetamine should be considered potentially toxic and correlated with the clinical circumstances.

Treatment of Patients with Phenethylamine Toxicity

Initial treatment of patients with toxicity from amphetamine derivatives should be directed toward assessment and stabilization of the airway, breathing, circulation, and temperature. Agitation and combativeness may make the initial evaluation and treatment of these patients difficult. Rapid control of the situation is essential because significant hyperthermia or other vital sign or laboratory abnormalities may require emergent therapy. Benzodiazepines (e.g., diazepam or midazolam) and butyrophenones (e.g., haloperidol or droperidol) have been recommended for agitation in these cases [86, 119] (Grade III recommendation). Diazepam decreased amphetamine- and methamphetamine-induced tremor,

piloerection, and seizures in rats but did not prevent death in one pretreatment model. In the same study, haloperidol, and to a lesser degree, propranolol decreased deaths in rats with amphetamine toxicity, but not those with methamphetamine toxicity. Haloperidol had no effect on seizures [120]. The ability of haloperidol to protect against amphetamine-induced mortality and the effect of diazepam on seizure reduction have been substantiated [121, 122]. In a retrospective human study, droperidol and lorazepam both reduced agitation, heart rate, blood pressure, and temperature, but lorazepam required more frequent dosing [123]. In patients with toxicity due to NBOMe or 2C class exposures, benzodiazepines were administered in 40% of cases [124]. Retrospective data reveal pediatric patients with methamphetamine toxicity treated with benzodiazepines and haloperidol recovered without adverse events [125]. There is significant potential for adverse drug effects when using butyrophenones including dose-dependent QT interval prolongation, reduction of seizure threshold, impaired heat dissipation, and dystonias [126–128]. Because of these potential complications, we consider benzodiazepines as the first-line agents for sedation. We recommend treatment with a benzodiazepine with a short time to peak effect, e.g., midazolam or diazepam. (Grade I recommendation based on animal data and III recommendation based on human data) [120, 122, 129]. Diazepam is preferred over midazolam due its longer half-life. (Grade III recommendation) [129] IV administration is ideal to achieve the most predictable pharmacodynamics, though midazolam can be given intramuscularly in cases where sedation is required prior to establishment of an IV. Initial doses of 5 mg diazepam IV or 5–10 mg midazolam IM should be administered with reevaluation in 10 min and further administration of repeat doses to achieve adequate sedation. (Grade III recommendation) [129]. Significant doses may be necessary to control the patient. Physical restraint of the patient may also be necessary until adequate sedation is achieved. Paralysis and endotracheal intubation are options for behavioral control and treatment of toxicity when other measures have failed. Patients with

hypoventilation or those without intact airway protective reflexes should also undergo endotracheal intubation. IV access should be obtained in all cases in which there are significant vital sign abnormalities or mental status changes. Patients should be placed on a cardiac monitor and administered oxygen as needed.

Hyperthermia (temperature > 40.5 °C) must be diagnosed rapidly and treated aggressively. Initial control of agitation must be definitively obtained in these circumstances to prevent further heat generation. A rectal temperature should be obtained to determine the accurate core temperature as an oral value can be falsely low due to tachypnea and poor technique. Vigorous use of benzodiazepines should be given simultaneously with cooling by ice water submersion. (Grade III recommendation) [130]. If this approach is not successful, the patient may require intubation and chemical paralysis to reduce muscular thermogenesis. Hyperthermia from methamphetamine and MDMA has been treated with risperidone in a pretreatment rat model, but it is unclear if any of the animal models mentioned above are applicable to humans [131, 132]. Acetaminophen, aspirin, and cooling blankets have little value in these circumstances. The use of dantrolene (see ► Chap. 142, “Dantrolene”) in toxin-induced hyperthermia has not been studied, but it may be administered if the above-listed measures have failed [133] (Grade III recommendation). In cases of significant temperature elevation, core temperature should be monitored with a continuous esophageal, rectal, or bladder probe, if available.

Gastrointestinal decontamination is not frequently an issue because many patients have used amphetamines by the intravenous or inhalational route. Nasal insufflation is not likely to be accompanied by a significant amount of drug in the gastrointestinal tract. In patients with a significant recent oral ingestion or in body packers/stuffers, gastrointestinal decontamination may be helpful. Gastric lavage is unlikely to be of benefit and should not be used. Activated charcoal delayed the onset to symptoms and reduced mortality when given after methamphetamine in a mouse model [134]. Activated charcoal

administration has not been shown to alter the outcome of these patients and given the risk of imminent seizures and subsequent loss of airway reflexes is not generally recommended. In the rare case of a patient with MDMA toxicity who presents within an hour of ingestion and is intubated for respiratory distress or behavior control, activated charcoal has some theoretical benefit.

Seizures should be treated initially with a benzodiazepine. (Grade I recommendation based on animal data and grade III recommendation based on human data). If seizure activity persists, phenobarbital or propofol should be added (Grade III recommendation), with airway protection as needed. Phenytoin will likely be ineffective in toxin-induced seizures. Continued seizure activity that is unresponsive to benzodiazepines and barbiturates, especially if it is contributing to significant hyperthermia, should be treated with neuromuscular blockade followed by electroencephalographic monitoring and consideration for general anesthesia. If focal neurologic deficits or persistent nonfocal findings such as coma are present, consideration should be given to the possibility of intracranial bleeding or infarction, and a computed tomography scan of the head is indicated.

Indications for ICU Admission in Amphetamine and Amphetamine-Derivative Toxicity

Clinically significant cardiac dysrhythmias

Cardiac ischemia

Severe hypertension ($\geq 200/125$ mmHg)

Coma

Intracranial hemorrhage/infarction

Intractable seizures

Agitation

Hyperthermia (≥ 40.5 °C)

Multisystem organ failure

Amphetamines cause a variety of dysrhythmias. Sinus tachycardia alone without hemodynamic compromise usually does not require specific treatment. Sinus tachycardia can be treated with sedation, volume resuscitation, and temperature control. Typically treatment with benzodiazepines will be most helpful, controlling

psychomotor and cardiac effects. Ventricular tachycardia, ventricular fibrillation, atrioventricular blockade, and QT prolongation are described as consequences of phenylethylamine toxicity [135, 136]. Standard advanced cardiac life support measures should be undertaken including antidysrhythmics, cardioversion, and defibrillation.

Agents with α -adrenergic antagonism, such as phentolamine (5 mg IV), or a titratable dihydropyridine calcium channel blocker such as nicardipine (5 mg/h IV infusion, increased by 2.5 mg/h every 15 min to a maximum of 15 mg/h) may also be helpful for vasospasm or complications of severe hypertension such as aortic dissection. Vasospasm may be recurrent and require prolonged therapy [137]. Nitroprusside (0.25 microgram/kg/min IV infusion, increased by 0.5 microgram/kg/min every 5 min to a maximum of 10 microgram/kg/min) and nitroglycerin (400 microgram sublingual tablet every 5 min or 50 microgram/min IV infusion, increased by 10 microgram/min every 5 min) can be titrated to effect in cases of elevated blood pressure with markers of injury to end organs such as cardiac enzyme elevation, acute kidney injury, neurological deficits, vision changes, or retinopathy or blood pressure $\geq 200/125$ mmHg.

Hypotension, if present, should be treated first with normal saline or lactated Ringer's solution. Hypotension unresponsive to crystalloid infusion requires the use of standard vasopressor agents.

Rhabdomyolysis, if present, should be treated with adequate hydration and maintenance of urine output. Although controversial, some clinicians recommend urinary alkalinization to prevent renal myoglobin deposition. Justification for this in the absence of clinical data showing improved outcomes includes the large quantity of IV fluids required to prevent oliguria in cases of significant rhabdomyolysis, the lack of significant adverse effect of bicarbonate infusion, and the expected development of hyperchloremic metabolic acidosis after significant normal saline infusion [138]. Alkalinization of the urine may impair renal clearance of the amphetamines, though. Given the lack of data suggesting benefit

of alkalinization over IV hydration in the treatment of rhabdomyolysis and decreased amphetamine clearance, we do not routinely recommend urinary alkalinization [138] (Grade III recommendation).

Elimination Enhancement

The enhanced renal elimination of amphetamines by urinary acidification is mentioned only to be immediately condemned. The elimination half-life of amphetamine is 8 – 10.5 h with acidic urine and 16 – 31 h with alkaline urine [139]. Toxicity from amphetamines may be accompanied by rhabdomyolysis, however, and the risk of inducing acute kidney injury due to the precipitation of myoglobin in acidic urine is believed to outweigh any potential benefit from increased drug clearance. Hemodialysis, hemoperfusion, and hemofiltration play no role in increasing drug clearance in amphetamine toxicity.

Criteria for ICU Discharge in Amphetamine and Amphetamine-Derivative Intoxication

- Hemodynamic stability
- Ability to protect airway
- Resolution of hyperthermia and lack of evidence of hyperthermia-related multisystem organ failure
- No requirement for continued intravenous medication infusion for hypertension, cardiac dysrhythmias, or seizures
- No evidence of continued drug absorption in cases of oral exposure
- Clear mental status
- Normal temperature
- No multisystem organ failure

Key Points in the Treatment of Amphetamine and Amphetamine-Derivative Intoxication

1. Rapidly gain control of agitated patients, using physical and pharmacologic restraint as needed.

2. Rapidly assess all vital signs, especially core temperature.
3. Treat hyperthermia aggressively with sedation, physical cooling measures, and paralysis, as clinically indicated.
4. Consider rhabdomyolysis as a complication of toxicity.

Special Populations

Pediatric Patients

Neonatal effects associated with maternal amphetamine use include tachycardia and bradycardia, which typically resolve as the drug is eliminated or as catecholamine homeostasis is restored. Infants born to amphetamine-using mothers may lag behind their peers in various measures of intellectual performance and show abnormal growth and maturation patterns at puberty [140]. Children also may ingest amphetamines unintentionally and may present a diagnostic dilemma to the clinician. In one series describing unintentional methamphetamine ingestion, children commonly manifested tachycardia, irritability, inconsolable crying, agitation, and vomiting [141]. These signs can mimic many serious childhood diseases. A urine toxicologic screen for amphetamines may be a valuable diagnostic tool in these cases, though evaluation of child abuse or parental negligence requires confirmation by gas chromatography mass spectrometry.

Pregnant Patients

Methamphetamine crosses the placenta rapidly in sheep and distributes into fetal tissues with a longer elimination half-life than in the mother. Doses similar to those seen in recreational use caused maternal and fetal hypertension and a decrease in fetal oxyhemoglobin saturation and arterial pH in this model [142]. Amphetamine use during pregnancy is associated with maternal hypertension, tachycardia,

proteinuria, premature labor, and placental hemorrhage in humans. Reported adverse pregnancy outcomes associated with maternal amphetamine use include cleft lip and palate, cardiac defects, growth retardation, cerebral hemorrhage, hyperbilirubinemia, biliary atresia, low birth weight, and reduced head circumference [140]. Preliminary data regarding prenatal exposure to MDMA indicate that there may be increased risk of cardiovascular and musculoskeletal abnormalities [143]. Few data exist regarding the effect of other phenethylamines in pregnancy; however, 2,5-dimethoxy-4-methyl-amphetamine was found to cause significant uterine and umbilical artery vasoconstriction and evidence of fetal distress in sheep [144].

Patients with Drug-Drug Interactions

Monoamine oxidase inhibitors, and possibly tricyclic antidepressants (catecholamine reuptake inhibitors), taken together with amphetamines may result in an exaggerated release of catecholamines and sympathomimetic toxidrome or serotonin toxicity/syndrome [145]. Similarly, antidepressants with serotonergic activity may increase clinical effects and toxicity that occur with MDMA and related drugs. Any drug or dietary change that results in alkaline urine (acetazolamide, antacid therapy, sodium bicarbonate) results in a decrease in the urinary clearance of amphetamine, although this effect is of little significance due to the baseline low urinary clearance of these drugs. Amphetamines are metabolized in part by the CYP2D6 enzyme. Users who are deficient in CYP2D6 activity (7% of Caucasians) or who are taking medications that are CYP2D6 inhibitors (e.g., paroxetine and fluoxetine) may be susceptible to increased toxicity from these drugs. This susceptibility may account for reported cases of toxicity with therapeutic or usual recreational doses of amphetamines and derivatives [67, 146]. In addition, amphetamines may inhibit the metabolism of other drugs that are metabolized by this cytochrome isoform [101].

Common Errors in the Treatment of Amphetamine and Amphetamine-Derivative Intoxication

Failure to rapidly detect and aggressively treat hyperthermia or other significant vital sign abnormalities because of violent behavior on the part of the patient

Failure to consider primary or secondary intracranial hemorrhage as a cause of mental status changes

Common Misconceptions about the Treatment of Amphetamine and Amphetamine-Derivative Toxicity

Alteration of urinary pH is useful in amphetamine toxicity.

All amphetamine compounds can be detected reliably by commonly available urine drug screens.

Legal action can be taken based on the results of an immunoassay screening test without confirmatory testing.

Fig. 1 Chemical structures of the primary arylcyclohexamines: phencyclidine, ketamine, and methoxetamine

Arylcyclohexamines (also known as arylcyclohexylamines) are a group of compounds that contain a cyclohexamine unit with an aryl moiety, typically a phenyl ring, attached to the same atom to which the amine group is linked (see Fig. 1). They all exhibit dissociative effects due to their antagonism of *N*-methyl-D-aspartate (NMDA) receptors, and many have been studied as alternatives to traditional anesthetic agents but subsequently abused recreationally in pursuit of these same effects. The most well-characterized arylcyclohexamines are phencyclidine ((1-(1-phenylcyclohexyl) piperidine; PCP)), ketamine, and, of the novel analogues, methoxetamine.

The main effects of this class of agents are nystagmus, hypertension, and tachycardia in a behaviorally disturbed, and possibly violent, patient. Variation in their potencies, tachyphylaxis in regular users, and the possibility of their misrepresentation as alternative arylcyclohexamines means that prognostication in these patients is difficult. While they can also cause seizures, coma, and death, the majority of patients presenting with acute arylcyclohexamine toxicity will survive with appropriate supportive care.

Historical Perspective

The first arylcyclohexamine to be described was 1-(1-phenylcyclohexyl) amine, in 1907, almost 50 years before the synthesis of PCP [1]. Other analogues reported in the early 1950s included *N*-ethyl-1-phenylcyclohexylamine (PCE) and 1-(1-phenylcyclohexyl)morpholine (PCMo). While many were not explored further by their

initial investigators, chemists at Parke-Davis pursued these and other derivatives in the ensuing years in the hope of developing new anesthetic agents. Compounds such as 1-[1-(thiophen-2-yl) cyclohexyl]piperidine (TCP) were investigated in clinical trials [2, 3]; however, none proved to be effective as an anesthetic due to their prominence of emergence delirium [4].

Phencyclidine, the first well-known arylcyclohexamine, was first synthesized by the Parke-Davis chemist Victor Maddox in 1956. While these experiments were not reported in the literature until nearly 10 years later [5], the pharmacology of phencyclidine had by then already been described [6, 7]. Initially promising human trials appeared to replicate the anesthetic effect observed in earlier animal studies, of potency in anesthesia, and an absence of respiratory depression, and PCP was approved by the US Food and Drug Administration (FDA) in 1957 under the trade name Sernyl [3, 8]. However, its adverse effects – including agitation, psychosis, and catatonia – were soon found to be more frequent and severe than anticipated, and Sernyl was withdrawn from clinical use in 1965 [9], though it was reintroduced to the veterinary market in 1967 as Sernylan [10].

Concurrent research by another Parke-Davis scientist, Calvin Stevens, led to the synthesis in 1962 of 2-chlorophenyl-2-methylamino-cyclohexanone, or ketamine [11–13]. The first human administration of ketamine was conducted in 1964 as part of a trial in 20 prisoner volunteers in the USA; it demonstrated that ketamine was an equipotent anesthetic agent to PCP with a reduced side effect profile, in particular with a reduced incidence of emergence delirium [9, 11]. The

study, led by Edward Domino at the University of Michigan, was the first to propose the use of the term “dissociative” in describing ketamine’s anesthetic effects. It was patented and subsequently marketed as Ketalar, having gained approval from the FDA in 1970 [3].

Since then, ketamine has evolved into a diversely utilized drug. Initially gaining widespread use in both human and veterinary anesthesia, its prevalence of emergence phenomena – though less than with PCP – has still largely restricted its human use to specific populations, in particular pediatric anesthesia and field medicine, where its hemodynamic stability and analgesic properties are highly valued. In veterinary medicine, ketamine remains the most widely used anesthetic across all animal species [14]. As further research into this multifaceted drug has progressed, its spectrum of human clinical use has also expanded. Known for decades as a potent analgesic, its use has recently become more common in the treatment of neuropathic pain, complex regional pain syndromes, and as an adjunct in postoperative pain relief [15–17]. While still somewhat experimental, it is also being researched as a treatment for severe depression and for refractory status epilepticus [18–27], and recent observational studies have suggested a potential role for ketamine as a rescue treatment for difficult-to-sedate patients with severe behavioral disturbance [28].

Recreational Use

Phencyclidine and ketamine appeared on the recreational drug scene at a similar time, with the first reports of recreational use of each drug occurring within a few years of each other in the 1960s [29–33]. First reported on the West Coast of the USA, the use of PCP spread rapidly across the USA such that in 1975 its use was described as an “epidemic of drug-induced schizophrenia,” owing to its overdose being responsible for more psychiatric admissions than alcohol abuse and schizophrenia combined [29, 30]. Between 1975 and 1977, the US Drug Abuse Warning Network (DAWN) reported a doubling in the number of

PCP-related emergencies and deaths, while 1978 data from the US National Institute of Drug Abuse (NIDA) reported that 13.9% of young adults (aged 18–25 years old) had used PCP [34]. Complicating its surveillance was its presence as an adulterant in up to 30 different street drugs, PCP being most commonly represented as marijuana [35]. One report of street drugs found on analysis to be PCP demonstrated less than 10% of samples had actually been sold as PCP [36]; more recently, PCP has been found in tablets sold as methylenedioxymethamphetamine (MDMA or “ecstasy”) [37].

It was not until April 1978, when all manufacture of PCP was prohibited in the USA under the Comprehensive Drug Abuse Prevention and Control Act of 1970, that its use began to decline [10, 38] and the subsequent cocaine epidemic of the 1980s eclipsed PCP use [38, 39]. In 1979, PCP was classed as a Class A drug of the UK Misuse of Drugs Act 1971 (the UK Misuse of Drugs Act 1971 prohibits the activities of Controlled Drugs in relation to their manufacture, supply, and possession; they are graded broadly into three classes, and penalties applied, based on the “harmfulness attributable to a drug when it is misused”) [40]

- **Class A** (includes): cocaine, heroin, lysergic acid (LSD), methadone, MDMA, morphine, PCP, and class B substances when prepared for injection
- **Class B** (includes): oral amphetamines, cannabis, codeine, ketamine
- **Class C** (includes): buprenorphine, benzodiazepines, tramadol, zolpidem

and made a Schedule 2 drug under the UK Misuse of Drugs Regulations 2001 (the UK Misuse of Drugs Regulations 2001 defines the classes of person authorized to supply and possess controlled drugs and defines the conditions under which they may be supplied, possessed, and prescribed [41]),

- **Schedule 1**: possession and supply are prohibited except in accordance with Home Office authority

- **Schedule 2:** are subject to full requirements of controlled drugs, including requirements for prescribing, safe custody, and the need to keep registers
- **Schedule 3:** are subject to prescription and safe custody requirements, however registers do not need to be kept
- **Schedule 4:** are not subject to prescription or safe custody requirements
- **Schedule 5:** are exempt from the above controlled drug requirements

as it was thought at the time that it might retain some medical indications; whilst not currently used as a pharmaceutical, PCP remains in Schedule 2 in the UK.

In 1971, the first account in the literature of ketamine's psychedelic effects was published in the *New England Journal of Medicine* [42]. Though recreational ketamine use was initially highest among healthcare professionals and others who had easy access to the drug [43], this changed in the 1980s and 1990s as it became increasingly popular among clubbers, and in particular on the rave scene, where it initially appeared as an adulterant to ecstasy tablets [44].

Despite early concern from the FDA about the misuse of ketamine, a request for control of its use from the US Department of Health and Services was rejected by the DEA [45], and it was not until 1995 that ketamine was added to the US "emerging drugs" list and eventually placed into Schedule III of the US Federal Controlled Substances Act (CSA) in 1999. In the UK, it was not until 2006 that ketamine was placed into Schedule 4 and added to Class C of the Misuse of Drugs Act, following evidence of continued abuse [40]; in June 2014, it was made a Class B drug and placed into Schedule 2 [46].

In the USA, increased control did not appear to be associated with a decline in ketamine use; this may, at least in part, relate to the burgeoning Internet trade providing a direct supply, particularly from sources in Hong Kong and in Mexico [47]. Today, most illicit ketamine originates from diverted pharmaceutical production or from illicit production in countries such as Mexico, China, India, and European states [48]. Internet trading

sites remain key in its distribution, the now obsolete Silk Road website having hosted numerous ketamine vendors.

First-Generation Arylcyclohexamine Analogues

Between 14 and 30 analogues of PCP have been reported, and while most of these did not reach a wide audience, the use of three became prominent: PCE, TCP, and 1-(1-phenylcyclohexyl) pyrrolidine (PCPy) [3]. PCE and TCP were the first of the PCP analogues to be reported, in street samples from Los Angeles in 1969 and 1972, respectively, with the first report of PCPy from Maryland in 1974 [36, 49, 50]. By 1975, TCP had been reported in 25 US states [30, 36, 51] and was the first of the arylcyclohexamines to be placed into Schedule I of the US CSA (the US Controlled Substances Act encompasses five Schedules of controlled substances (I–V) based on three criteria [52]. In 1975, after it was deemed to be of no medical value and of high abuse potential [45]:

- (a) A drug or substance's potential for abuse
- (b) A drug or substance's role in currently accepted medical use in treatment in the USA
- (c) A drug or substance's potential to lead to psychological or physical dependence

PCE and PCPy followed suit in 1978, both having been associated with increasing use and fatalities [45, 53, 54]. Anecdotal reports suggest that, despite their scheduling, all three analogues remained available throughout the 1980s, with the last reported seizure of PCE in 1991 [3]. The synthesis of TCP, meanwhile, has been described as recently as 2004 on an online drug forum [55]. Though their potencies were thought to be similar, users describe TCP and PCE as more potent than PCP, with TCP having a longer duration of action [3], while PCPy is reported to be roughly equipotent to PCP [4, 56].

The ketamine analogue 2-(ethylamino)-2-thiophen-2-ylcyclohexan-1-one (tiletamine) was developed by Parke-Davis for use in veterinary

Fig. 2 Chemical structures of the arylcyclohexamine analogues

anesthesia and was patented in 1966 [57]. Despite being placed in Schedule III of the US CSA in 1987, there are reports of tiletamine misuse in the USA and South Korea, including two fatalities from its overdose [58, 59].

Other compounds, such as the PCP precursor 1-piperidinocyclohexanecarbonitrile (PCC), have relevance due to their detection as contaminants. An intermediary in the synthesis of PCP, the presence of PCC indicates an incomplete synthetic process and has been found as a contaminant in up to 33% of illicit PCP samples [49, 60, 61]; reports of an incorrectly synthesized batch of PCP was reported to have caused abdominal cramps, vomiting, coma, and even death [62]. Two studies in mice have shown conflicting data: one showed PCC to be roughly equipotent to PCP, while the other found PCC to be almost twice as toxic as PCP, with an LD₅₀ of 155 µmol/kg compared to an LD₅₀ of 283 µmol/kg for PCP [63, 64]. This toxicity is thought to be due to the release of hydrogen cyanide [61, 63, 65].

Novel Arylcyclohexamine Analogues

More recently, clandestine chemists have been producing novel analogues of phencyclidine and ketamine. A true example of the flourishing “designer drugs” scene, the theoretical effects of the ketamine analogue methoxetamine (MXE), or 2-(3-methoxyphenyl)-2-(ethylamino)cyclohexanone (see Fig. 2), were described on online forums in 2006, at least 3 years before its first known synthesis [3]. It was not until May 2010 that the first public report of MXE’s effects was described online, and only a few months later, it was marketed via “research chemical” websites as a “bladder friendly” alternative to ketamine (see below). First reported to the Early Warning System at the European Monitoring Centre for Drugs and Drugs Abuse (EMCDDA) by the UK in November 2010 [48], availability escalated quickly, with up to 58 websites offering MXE by July 2011 [66]. The first report of MXE toxicity in the scientific literature was published in August 2011 [67], with further reports of acute MXE toxicity and

MXE-related fatalities subsequently reported [68–74]. In April 2012, MXE became the first drug in the UK to be banned under a Temporary Class Drug Order (TCDO) [75, 76]; later that year, the UK Advisory Council on the Misuse of Drugs (ACMD) formally recommended that MXE was controlled, and in February 2013, it was placed into Schedule 1 as a Class B drug under the UK Misuse of Drugs Regulations 2001 and Misuse of Drugs Act 1971, respectively [75, 77].

Further methoxylated arylcyclohexamine analogues have emerged in addition to MXE. While they have appeared on the recreational drug scene only recently, their initial descriptions date back to the first description of PCP, with 2- and 4-methoxy-phencyclidine (2-MeO-PCP and 4-MeO-PCP [also methoxydine]) described by Maddox in his 1965 report [5]; 14 years later, 3-methoxy-phencyclidine (3-MeO-PCP) was described by Geneste et al. [78]. Little was heard of these compounds until their effects were described on an online forum by Beagle in 1999 [79, 80]; however, this site was taken offline in 2004. They reemerged again in December 2008, when 4-MeO-PCP appeared for sale online in the UK, with reports suggesting its varied potency to be due to impurities between batches and leading to re-experimentation with 3-MeO-PCP, which was made available online in April 2011 [3]. 4-MeO-PCP was first reported to the EMCDDA in January 2011 by Finland, with its first involvement in a polydrug intoxication reported in August 2011 from Norway; 3-MeO-PCP was first reported to the EMCDDA in March 2012 by the UK [81].

The ban on MXE left a void in the UK designer drug, or “research chemical,” scene which was quickly filled by other aryl-aminocyclohexanone analogues. In May 2012, 2-(2-methoxyphenyl)-2-(methylamino)cyclohexanone, or 2-methoxy-ketamine, came on to the market followed closely by *N*-ethyl-norketamine (*N*-EK) in August of the same year [3]; they were reported to the EMCDDA in August 2012 by Sweden and in September 2012 by the UK, respectively [82]. Their potency was reported by users to be low, with a wide variation in their effects.

Although other arylcyclohexamine analogues exist (see Fig. 2), including some of those mentioned here, most are poorly characterized and hence not discussed further.

Epidemiology of Recreational Use

Today, recreational use of arylcyclohexamines continues throughout the world. Without clear reason, PCP remains most popular in the USA and Canada – indeed, its use is almost exclusive to North America – with 2013 data showing 6.5 million Americans (2.5%) aged 12 and older to have used it in their lifetime, compared with 2.7 million (1.0%) for ketamine [83]. Ketamine is more widely used in the UK, however, and overall it retains a much more international presence on the recreational drug market; the 2015 UN World Drug Report reported its use in 58 countries [84].

In both the USA and the UK, the use of arylcyclohexamines is more common among males than females [83, 85, 86]: in the UK, 3.6% of males report lifetime ketamine use compared with 1.3% of females; in the USA, this is 1.3% compared to 0.8% [83, 87]. Available data from the UK shows that ketamine use is higher in gay or bisexual males (4.2%) than in gay or bisexual females (1.5%) and heterosexual adults (0.4%) [88]. Like many other recreational drugs and novel psychoactive substances, the use of arylcyclohexamines is more common among nightclub attendees [89–91].

Phencyclidine and Ketamine

Despite the decline of PCP use in the 1980s after its ban in 1978, it has remained a consistently available street drug in the USA, though its use reached a nadir in 1984 [92]. Data from the 2013 US National Survey on Drug Use and Health (NSDUH) shows that lifetime use of PCP in the USA has remained relatively constant over the past decade, at around 2.5% of the population [83]. Of concern, however, is data from the DAWN, which showed a fivefold increase in the number of PCP-related presentations to

emergency departments in the USA between 2005 and 2013, from 14,825 to 75,528 [93]. However, NSDUH data showed a decline in PCP use between 2012 and 2013, with past year initiates and prevalence of last year use falling from 90,000 to 32,000 and 172,000 to 90,000 (0.1% of the population), respectively. In contrast to the diversion of ketamine from overseas suppliers, manufacture of PCP has remained localized, providing one explanation for the sudden decline in use between 2012 and 2013: the discovery and bust of the largest-ever PCP laboratory on US soil in Los Angeles in February 2012 [94]. Of concern, despite the significant fall from 2012 numbers, is that in 2013 more than half (19,000 of 32,000) of past year initiates of PCP use were aged between 12 and 17 years.

Between 2006 and 2013, lifetime ketamine use in the USA has remained steady, at 0.9–1.0% of the population [83], though there was a significant increase in the lifetime use among those 26 years of age and older (0.7–1.1%) and a significant decrease in lifetime use among those aged 18–25 years (2.8–1.5%) and those aged 12–17 years (0.3–0.2%). Despite the overall lifetime use of ketamine remaining steady, there has been a similar increase in US emergency department visits due to ketamine, from 303 in 2005 to 1,550 in 2011 [93]. Further, while lifetime PCP use remains two-and-a-half times higher than lifetime ketamine use in the USA, the most recent data from NIDA's Monitoring the Future Study shows a trend among school-aged users toward ketamine rather than PCP, with 1.5% and 0.8% of 12th graders reporting last year use of ketamine and PCP, respectively, in 2014 [95].

In the UK, data from the Crime Survey of England and Wales (CSEW) showed last year use of ketamine in those aged 16–59 years increased from 0.4% to 0.6% between 2012/13 and 2013/14, with a significant increase in use seen in those aged 16–24 years (0.8–1.8%) [86]. Lifetime use among 16–59-year-olds increased from 1.3% to 2.7% between 2006/07 and 2013/14. Among self-reported substance users in the 2014 Global Drugs Survey, 5.7% of 78,819 global respondents reported last year use of ketamine; this was highest in the UK (19.8% of

7,326 respondents), while it did not make the list of top 20 drugs used in the USA among its 6,500 respondents [96]. Data from the European Drug Emergencies Network showed ketamine accounted for 2.0% of the 5,529 reported presentations of acute recreational drug toxicity to 16 emergency departments in 10 European countries [91]; 0.5% of self-reported ketamine users in the 2015 Global Drugs Survey had sought emergency medical treatment in the past 12 months [97].

In Hong Kong and China, ketamine has for over a decade been the most commonly used psychotropic drug – and second most common drug of abuse overall, behind heroin – since overtaking ecstasy in 2001 [98]. Among reported drug abusers (0.14% of the total population), 28.2% reported ketamine use in 2013, down from a peak of 37.9% in 2009 [99]. Its use is particularly evident among drug abusers under the age of 21 and among newly reported drug abusers; since 2001, in both groups, ketamine has been the most widely reported drug of abuse: in 2013 representing 52.5% (from a peak of 85.5% in 2008) and 46.4% of users, respectively [98, 99]. Similarly to US and UK data, ketamine use was more than twice as common in males, who represented 73% of ketamine users.

Arylcyclohexamine Analogues

There is no population level data on the prevalence of use of MXE from surveys such as NSDUH in the USA or CSEW in the UK. Figures regarding the use of MXE are therefore limited to targeted, nonrepresentative surveys among specific subpopulation groups. In 2011, the annual online Global Drugs Survey reported last year use of MXE in 4.2% of 7,700 UK respondents [100]; in an in situ survey of nightclub attendees in South London, UK, the prevalence of last year use of MXE was 6.4% [90]. Data from the UK National Poisons and Information Service (NPIS) showed a total of 345 inquiries regarding MXE between April 2010 and August 2012. There was a significant decrease in the number of inquiries to the NPIS in the 3 months following

Table 1 Characteristics of the major arylcyclohexamines

	PCP [38, 43]	Ketamine [102]	Methoxetamine [48]
Molecular structure	1-(1-phenylcyclohexyl) piperidine	2-chlorophenyl-2-methylamino-cyclohexanone	2-(3-methoxyphenyl)-2-(ethylamino)cyclohexanone
Molecular weight	243 kDa	238 kDa	247 kDa
Presentation	All available as white powder, liquid, tablets, and capsules		
	Often sprayed onto leaf material and smoked	Often adulterated (caffeine, MDMA, heroin, cocaine [CK])	Sprayed on to plant material and smoked
Common street names	Angel Dust, PeaCe Pill, Tic Tac, Supergrass, Hog, Shermans	Special K, Ket, vitamin K	Special M, Mexxy, M-ket, Kmax

MXE receiving a TCDO in April 2012 compared with the 3 months preceding the TCDO, with the total number of inquiries falling from 166 to 35 [85].

The only published data on the use of other novel arylcyclohexamine analogues are for 3- and 4-MeO-PCP, from the Swedish STRIDA project [101]. Between January 2010 and June 2013, only five inquiries were made to the Swedish Poisons Information Centre relating to “PCP” intoxication (none of these were analytically confirmed). In the 21-month period from July 2013 to March 2015, of a total of 2,687 consultations for suspected intoxication with a new psychoactive substance (NPS), 80 cases (3.0%) were registered as 3-MeO-PCP, 4-MeO-PCP, or PCP intoxication. Blood and/or urine samples were available for analysis in 30 (37.5%) of these cases: 27 (90.0%) were confirmed to involve 3- and/or 4-MeO-PCP; none tested positive for PCP. A total of 1,243 cases during the 21-month study period were analyzed for the presence of an NPS. 3-MeO-PCP and 4-MeO-PCP were detected in 56 (4.5%) and 11 (0.9%) of cases, respectively; both substances were found in 8 (0.6%) of cases [101]. The total of 59 cases in which either 3- and/or 4-MeO-PCP were detected suggests there is the potential that, like PCP and ketamine before them, they may also exist as adulterants to other drugs.

Chemistry and Clinical Pharmacology

The structure of arylcyclohexamines consists of a cyclohexamine unit with an aryl moiety, typically a phenyl ring, attached to the same atom to which

Table 2 Structural differences between ketamine and phencyclidine and pharmacodynamic effects

	Modification	Effect
1	Replacement of piperidine ring by a methylamine	Increased nausea
		No effect on potency
2	Addition of chloride to the phenyl ring at the 2-position	Decreases potency
		Increases analgesic effect
3	Addition of carbonyl group to the cyclohexal ring	Increases elimination with subsequent decrease in duration of action

the amine group is linked (see Fig. 1). Their characteristics are summarized in Table 1.

Chemical Structure

Ketamine and methoxetamine differ from phencyclidine in a number of ways (Tables 2 and 3 and Figs. 1 and 2) [76]. Unlike phencyclidine, ketamine has a chiral center and exists as two optical enantiomers that exhibit different properties. The S(+)-enantiomer has more potent analgesic effects, owing to its fourfold greater affinity for the NMDA receptor, while the R(–)-enantiomer is associated with more agitation due to its more prominent postsynaptic effects [103–105]. Studies of ketamine anesthesia for surgery in rats have also demonstrated the R(–)-enantiomer to be responsible for an increased incidence of emergence reactions than either racemic or S(+)-ketamine [106–108]. Differences in the metabolism of the optical isomers and their metabolites’

2	Addition of 3-methoxy group to the phenyl ring	Increased μ -receptor affinity Removes mood-altering effects

subsequent biodisposition have also been reported; however, the significance of this has not been well characterized [103]. Methoxetamine also exists as two optical enantiomers; however, it is not known whether there are significant differences in their pharmacokinetic or pharmacodynamic properties.

Although, as discussed earlier, there are many other arylcyclohexamine analogues that have been used recreationally, there is limited data available on their pharmacology.

Pharmacokinetics

Phencyclidine is rapidly absorbed from the respiratory and gastrointestinal tracts, with an onset of action that is quickest after intravenous (i.v.) or inhalational routes (2–5 min) and slowest following oral use (30–60 min) [109, 110]. While oral bioavailability of up to 70% is reported, the typical dose to achieve sedation equivalent to 0.25 mg of i.v. PCP is up to 20 times higher for the oral route (1–5 mg) [38]. Unlike PCP, ketamine is not well absorbed by the oral route and undergoes significant first-pass metabolism, with an oral bioavailability of less than 20% [111–113].

Arylcyclohexamines are weak bases with a pKa of 7.5–8.5 and molecular weights ranging from 238 to 247 kDa. PCP has a larger volume of distribution than ketamine because it is more lipophilic, and this contributes to its longer half-life and duration of action of between 7 and 46 h, compared with a half-life of 3 h for ketamine [38, 109]. Both PCP and ketamine are highly lipid soluble, enabling efficient distribution to the

Table 4 Onset and duration of effects (in minutes, unless specified)

Oral	60–180	60–120	180–300

central nervous system (CNS), and water soluble, allowing them to be administered by a variety of routes. The onset of action of ketamine and MXE, as for PCP, is rapid following i.v. and intramuscular (i.m.) administration, with effects apparent after 1 and 5 min, respectively [114]. In contrast to PCP, the onset of action of ketamine following nasal insufflation is up to 30 min, while users report that for MXE, this is as long as 30–90 min [114]. Duration of effect by different routes of administration is shown in Table 4.

All arylcyclohexamines are metabolized by the hepatic microsomal oxidizing system. PCP is metabolized by isoenzymes from the CYP3A and CYP2B subfamilies, primarily by hydroxylation to various inactive metabolites [43, 117, 118]. Metabolism of ketamine is primarily by the CYP2B6 isoenzyme, with contribution from CYP3A4 and CYP2C9 [119].

The main pathway of ketamine metabolism is by *N*-demethylation to norketamine, its major metabolite and also a noncompetitive NMDA receptor antagonist. Norketamine has one-third the potency of ketamine [38, 120] and, like its parent compound, exhibits chiral properties: its S (+)-enantiomer having greater affinity for the NMDA receptor than its R(–)-enantiomer [121]. Norketamine undergoes hydroxylation at the hexanone ring (this hydroxylation also being a minor metabolic pathway of ketamine itself) and subsequent glucuronidation to more water-soluble

Table 5 Pharmacokinetic properties of the arylcyclohexamines

	Phencyclidine [38, 110, 124]	Ketamine [38, 102, 112]	Methoxetamine [77, 100]

metabolites that are excreted in urine. There does not appear to be significant differences in the pharmacokinetics between ketamine's two enantiomers [104], although some studies have reported a longer elimination half-life for S(+)-ketamine of up to 4–7 h [122].

No human studies have investigated the metabolism of MXE; the little information that is available is based on in vitro studies using liver microsomes and rat models [77, 123]. These showed the predicted metabolism of MXE by CYP 2B6 and CYP3A4, with the main metabolite, normethoxetamine, resulting from *N*-deethylation and accounting for over 70% of metabolites; the other major pathway resulted in *O*-desmethylmethoxetamine and accounted for 14% of metabolites. As with norketamine, normethoxetamine then undergoes hydroxylation and glucuronidation to form the more water-soluble hydroxynormethoxetamine glucuronide. These metabolites are consistent with those found in urine samples of analytically confirmed MXE

ingestions [70, 77, 123]. Like norketamine, normethoxetamine is thought to be pharmacologically active; however, this is unproven.

Known pharmacokinetic properties of the arylcyclohexamines are shown in Table 5.

Pharmacodynamics

All arylcyclohexamines exhibit dissociative effects due to their noncompetitive antagonism of glutamate receptors of the NMDA subtype [125]. They were initially sought after as an alternative to more traditional anesthetic agents but subsequently abused recreationally in pursuit of these same effects. Ketamine has approximately 10% of the affinity for the NMDA receptor than PCP [119, 125, 126], while 3-MeO-PCP has been found to have almost three times the affinity of PCP for the NDMA receptor [127]. In addition, the arylcyclohexamines also have effects at many non-NMDA receptors (Table 6).

Arylcyclohexamines cause dissociation between the somatosensory cortex and higher brain centers, evoking a cataleptic state in which there is an absence of motor reaction to nociceptive stimuli [128, 129]. Functional magnetic resonance imaging (fMRI) studies have demonstrated a dose-dependent reduction in pain-induced cerebral activation at the secondary somatosensory cortex (S2), the insula, and the anterior cingulate cortex [130, 131]. While cortical effects are predominant, arylcyclohexamines also have significant effects at the spinal level, blocking afferent spinoreticular pathways and enhancing descending inhibitory serotonergic pathways [132–135].

Glutamate-Dependent Mechanisms

Glutamate is the major excitatory neurotransmitter in the mammalian CNS, acting on pre- and postsynaptic receptors located on ion channels [102]. Ionotropic glutamate receptors are classified as either NMDA, activated specifically by *N*-methyl-D-aspartate, or non-NMDA, activated by other neurotransmitters such as AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) or kainate [136, 137]. NMDA receptors are located on nearly all CNS cells, and in particular on those structures involved with nociception [102]. A specific “PCP binding site” has been identified; of the major arylcyclohexamines, PCP displays the highest

affinity for this site, followed by methoxetamine and then ketamine [127] (Table 6).

Activation of NMDA receptors occurs after calcium-dependent exocytosis of glutamate-containing synaptic vesicles [138, 139]. Glutamate is released into the synaptic cleft where it binds postsynaptic NMDA receptors, opening ion channels, and leading to membrane depolarization [140].

The NMDA Receptor

Present on nearly all cells of the CNS, the NMDA receptor is a tetrameric structure consisting of two subunits, of which there are three types: NR1, NR2, and NR3 (alternatively known as GluN1, GluN2, and GluN3, respectively) [102]. Each subunit possesses four hydrophobic segments, M1 to M4, which form the transmembrane domain (TMD); three of these segments (M1, M3, and M4) are truly transmembrane, while the M2 segment faces the cytoplasm and forms the receptor’s ion channel (Fig. 3). As well as the TMD, the NMDA receptor is comprised of two extracellular domains: the N-terminal domain (NTD, or amino terminal domain [ATD]) and the ligand-binding domain (LBD) [102, 139, 141].

The NMDA receptor is typically comprised of two NR1 and two NR2 subunits, of which seven and four subtypes of each subunit have been identified: NR1 a-g and NR2 A-D. The NR2 subtypes appear to be responsible for the variation in potency between arylcyclohexamines and the

Fig. 3 Structure of the tetrameric NMDA receptor. Each of the two subunits (in this case NR1 and NR2) comprise a transmembrane domain (TMD), containing segments 1–4, and two extracellular domains: the ligand-binding domain (LBD) and the amino terminal domain (ATD). The channel-blocking domain (C; site of Mg^{2+} ion voltage-dependent block) and sites of glutamate (Glu) and glycine (Gly) binding are also shown. The PCP binding site is not shown but is located close to the Mg^{2+} binding site (C) within the ion channel [102, 139] (Figure reproduced with kind permission from Prof. David Lodge)

pathological processes associated with abnormal NMDA channel function [102, 142–144]. While the NR2A subtype is ubiquitous, the locations of the other subtypes are more localized. The NR2B subtype is found in the anterior parts of the brain, especially the cingulate cortex, hippocampus, amygdala, and olfactory bulb, and is also involved in nociceptive transmission to the thalamus, spinal cord, and extrasynaptic areas such as the primary afferents. The NR2C subtype is prominent in the cerebellum, while the spinal cord is rich in the NR2D subtype. Studies of PCP and ketamine have shown that they are, respectively, four and nine times more potent at NR2B-D receptor subtypes compared with the NR2A receptor subtype [142]. While there are no receptor studies of MXE, there is the potential that, given reports of cerebellar features in patients with acute MXE toxicity [69], it has greater specificity for the NR2C subtype.

NMDA receptors are coupled to calcium ion channels, which are activated by synaptic glutamate binding to the LBD of the NR2 subunit and require co-activation with either glycine (or D-serine) binding to the LBD of the NR1 subunit. The main inhibitory mechanism is the voltage-dependent block of the ion channel by magnesium ions [145]. At resting membrane potential, extracellular magnesium is held within the ion channel by negative electrostatic forces; neuronal depolarization causes magnesium to be released, and in the presence of the co-agonists glutamate and glycine, calcium influx ensues. Predictably, ketamine and magnesium have been shown to have a synergistic antagonistic effect at NMDA receptors [146].

The effects of NMDA receptor antagonism by arylcyclohexamines result in modulation of glutamatergic transmission [147]. Their primary effects, including anesthesia, analgesia, and psychotomimetic properties, relate to this action (see Pathophysiology, below). Other effects thought to be related to the NMDA receptor include antidepressant activity [148] and specific analgesic effects due to action at NMDA receptors in dorsal horn neurons [149].

Non-glutamate/NMDA-Dependent Mechanisms

Arylcyclohexamines also display affinity for a host of other receptors (Table 6). They bind to and inhibit biogenic amine transporters at approximately 10–20% of their affinity for the NMDA receptor [150], with resultant sympathomimetic and psychomotor effects due to inhibition of catecholamine, serotonin, and dopamine reuptake. It is thought that the effect on dopamine release is especially prominent in the nucleus accumbens [151], with subsequent implications for addiction [152]. In addition to inhibition of amine transporters, arylcyclohexamines have been demonstrated to have varying affinity for D_2 and 5-HT_{2A} receptors, where they are thought to exert agonist activity [153]. PCP and MXE have greater affinity than does ketamine at the 5-HT_{2A} receptor, thought to be related to the more

pronounced perceptual disorders and hallucinations seen with their use [154].

In overdose, the arylcyclohexamines also stimulate sigma receptors [155], causing an inhibitory effect on cholinergic pathways. It is thought that binding of sigma receptors may play a role in their antidepressant activity [156]. While ketamine has also been shown to bind to opioid receptors, its binding affinity at usual recreational or anesthetic doses is too low to contribute to its analgesic effects [157, 158]. Arylcyclohexamines also display weak affinity for nicotinic and muscarinic cholinergic receptors [157], though their role here is uncertain.

Analgesic Effects

As mentioned, the arylcyclohexamines are weak agonists at opioid receptors; however, at usual anesthetic and recreational doses, this is not thought to contribute to their analgesic effect; further, their analgesic effects are not reduced by the administration of naloxone [160, 161]. Rather, their analgesic properties are modulated by NMDA receptor antagonism in the CNS and in the spinal cord, by decreasing the amplification response to repeated stimulation, or “windup,” that causes CNS sensitization to nociceptive stimuli [102, 122]. Studies of ketamine have also suggested a non-NMDA-dependent role in directly inhibiting nitric oxide synthase, contributing to its analgesic effect [162, 163]. Further, both NMDA- and nitric oxide-dependent mediation of opioid receptors, and in particular the μ -receptor, appear to attenuate analgesic tolerance [164].

The Pharmacology of Tolerance, Dependence, and Withdrawal

The stimulatory effects of the arylcyclohexamines on dopaminergic and serotonergic transmission in the central nervous system, via both inhibition of amine transporters and via direct agonist activity at D_2 and 5-HT_{2A} receptors, are responsible for their addictive properties [151–153].

While it was initially thought that PCP did not have dependence potential, subsequent animal studies found that monkeys self-administered PCP and appeared to develop withdrawal [165]. These studies have since been replicated, demonstrating the development of dependence and the presence of withdrawal in multiple animal species [166–171]. In a case series of 68 chronic PCP users seeking treatment who had used PCP for a mean of 3.0 years, it was found that both psychological and physical dependence and withdrawal occurred [172]; 25 (36.8%) had considered themselves to be addicted to PCP. The most commonly reported symptoms were craving (51.5%), increased need for sleep (48.5%), poor memory (45.6%), depression, and laziness (both 44.1%). Irritability was reported by 30.9%, increased anxiety by 22.1%, and headaches and insomnia by 16.2% and 14.7%, respectively. However, no details regarding the length or severity of these symptoms were reported.

Ketamine use has been reported to be characterized by bingeing, often with repeated dosing until exhaustion of a user's supply [173, 174], and is generally associated with psychological dependence characterized by craving, rather than any physical dependence or withdrawal state [175–177]. In an online survey of 506 mostly Spanish self-reported ketamine users, 40.5% reported tolerance with ketamine use [178]. The observed tolerance in repeat and chronic ketamine users is thought to be as a result of auto-induction of CYP450 enzymes [177, 179–181].

No studies have examined the dependence or abuse potential of MXE; however, self-reports from users suggest compulsive re-dosing is an issue [48]. Reported withdrawal symptoms of MXE include low mood and depressive thoughts, while one user reported 48 h of insomnia after nasal insufflation of 1,000 mg of MXE [114].

Pathophysiology of Toxic Effects

The effects of the arylcyclohexamines are varied owing to their interactions with numerous receptors, as detailed above. Their predominant effects are on the central nervous system, and their

induction of a state akin to catatonia has led to advancements in the pathophysiology of schizophrenia, with NMDA receptor dysfunction as the foundation of the glutamate hypothesis of schizophrenia [147, 182, 183].

Neurological Effects and Pathophysiological Similarities with Schizophrenia

While the clinical effects of the arylcyclohexamines have been apparent from their outset, it has been only recently that their effects on the NMDA receptor have been fully characterized, their schizophrenia-like effects noted, and the glutamate hypothesis of schizophrenia advanced.

In the 1960s and 1970s, observations of dopamine D₂ antagonists, such as chlorpromazine, causing reduced psychotic features led to the development of the dopamine hypothesis of schizophrenia [184]. Characterized by positive symptoms – including delusions, hallucinations, and catatonia – and negative symptoms – of alogia, avolition, and flattened affect – there has been ongoing debate as to the ability of a hypodopaminergic state to account for all these effects [185].

More recently, the hypothesis of glutamate dysfunction as an explicable mechanism for both the positive and negative symptoms of schizophrenia has gained support [182]. While the schizophrenia-like effects of PCP were noted early in its use [11, 29, 186–188], the subsequent elucidation of the mechanisms of the NMDA receptor function has led to further interest in the role of this receptor and its antagonists as a model for studying schizophrenia and possible therapeutic interventions [185, 189]. Studies have shown that arylcyclohexamines produce a dose-dependent transient psychosis-like state closely resembling schizophrenia [147, 183, 190–192], which in some cases is indistinguishable from it [193] and indeed can exacerbate symptoms in those with schizophrenia [191, 194, 195].

These effects appear to be mediated by changes in blood flow seen in the prefrontal, medial frontal, and inferior frontal cortices [196, 197]. Though

the fundamental action of arylcyclohexamines in their antagonism of NMDA receptors is reduction in glutamatergic transmission at this receptor site, it has been shown that many of their effects are actually affected by an *increase* in non-NMDA-mediated glutamatergic activity. This goes some way in explaining the behavioral and neurochemical dysfunctions of arylcyclohexamine use while also providing an explanation for the apparently paradoxical pro-convulsant properties of high doses of PCP despite decreased NMDA-associated glutamatergic activity [198]. That is, the primary antagonism of NMDA receptors leads to decreased stimulation of inhibitory GABAergic interneurons (causing decreased GABA release), with subsequent increase in not only downstream glutamate release but also increased cholinergic and serotonergic activity [199–201]; these effects are seen primarily in the frontal cortex, anterior thalamus, and the superior temporal, posterior cingulate, and parahippocampal gyri. These effects on the pyramidal cells of the posterior cingulate cortex, in particular, may account for the focal neurodegeneration seen with chronic ketamine use due to this over-excitatory effect [199].

Further sequelae of chronic use include dose-dependent loss of gray matter volume and white matter abnormalities in the frontal lobes [202, 203]. Chronic use has also been found to induce regionally selective upregulation of dopamine D₁ receptors in the dorsolateral prefrontal cortex [43]. Further, consistent with the alternate dopamine hypothesis, acute ketamine administration has also been shown to alter the firing of mesocortical and mesolimbic dopaminergic neurons, leading to increased extracellular dopamine in both the striatum and in the prefrontal cortex [204, 205].

Other mechanistic links between the NMDA receptor and schizophrenia have been demonstrated in the signal transduction cascades that mediate cellular growth, differentiation, and survival in proliferating mammalian cells. In particular, the Ras–MAPK pathway has been shown to be involved in NMDA receptor signaling, providing a regulatory role in the synaptic plasticity related to long-lasting changes on memory and

addiction [206]. While formal studies of the molecular mechanisms of cognitive deficits due to arylcyclohexamine use are lacking, the similarity between the memory impairment seen in chronic users of ketamine and in schizophrenics suggests that the dysfunction of the MAPK pathway and decreased MAPK1 gene expression in schizophrenic brains [206–208] may also play a role in the cognitive and memory deficits seen with chronic arylcyclohexamine use [209, 210].

Differences Between Acute and Chronic Use

While there have been many reports of the psychotic effects attributable to acute arylcyclohexamine use, differences in the neuropathophysiology in repeated and chronic users have been shown to induce more persisting schizophreniform symptomatology [147].

As mentioned above, increase in blood flow to the frontal cortex is seen after acute ketamine exposure in both healthy volunteers and in schizophrenic patients [196, 197]; in contrast, a reduction in frontal lobe blood flow is seen in long-term abusers of PCP [211, 212], more consistent with the “hypofrontality” observations of cognitive dysfunction associated with reduced blood flow to the frontal cortex in schizophrenia [213–216].

Similarly, there is a difference in the effects on dopaminergic transmission associated with acute and chronic arylcyclohexamine use. Where their acute administration resulted in a dramatic increase in frontal lobe dopaminergic activity [204, 217, 218], long-term administration caused the reverse effect [219, 220], again consistent with effects seen in schizophrenia [221, 222]. The increase in dopamine in the forebrain is responsible for the cognitive dysfunction seen after acute arylcyclohexamine ingestion due to impairment of spatial working memory [223, 224]. Alongside this, the disinhibition of prefrontal glutamatergic transmission caused by NMDA receptor blockade leads to increased downstream glutamatergic stimulation of mesocorticolimbic dopaminergic transmission and of locomotor behavior [225].

The subsequent reduction in dopaminergic activity seen with chronic use of arylcyclohexamines also plays a role in decreased working

memory function of the prefrontal cortex [226]. In addition to the cortical effects of NMDA receptor antagonism, studies of subcortical striatal dopamine dysfunction have revealed more about dopamine’s role in the impaired cognitive function seen in schizophrenia and in chronic arylcyclohexamine use. In subcortical areas, it is thought that dopaminergic hyperactivity is in fact associated with chronic use [147]; this has previously been suggested for schizophrenia and would be consistent with the original dopamine hypothesis [227–229].

While the acute administration of arylcyclohexamines increases serotonergic and catecholamine activity via both biogenic amine reuptake inhibition and direct receptor agonism, no changes in their metabolism have been observed after long-term use of PCP [219, 220]. The effects of chronic arylcyclohexamine use on cholinergic pathways are less well studied, though it is thought that a degree of tachyphylaxis occurs [230].

Cerebellar Effects

While the effects of PCP and ketamine on the cerebellum have been demonstrated *in vitro* in rats, this clinical effect has not been demonstrated in humans [177]. In contrast, cerebellar toxicity was a prominent feature in a three cases of acute MXE toxicity, who presented with incoordination and severe cerebellar signs of ataxia, dysidiadokinesis, and nystagmus [69]. In all of these cases, the route of administration had been by nasal insufflation, with cerebellar toxicity reported within 20–30 min; in two of these, cerebellar features resolved after 16 h; however, in one case, ataxia and nystagmus persisted for 4 days. Toxicological analysis of serum samples of these patients showed methoxetamine concentrations of between 0.16 and 0.45 mg/L; no other drugs, including ethanol, were detected in any of these cases.

Effects on the Cardiovascular System

Pressor Effects

The pressor response typical of arylcyclohexamines has long been observed, with positive

effects on blood pressure as well as potentiation of the response to catecholamines, though tachyphylaxis was noted with repeated dosing [6, 7, 231]. While the mechanisms were not known at the time, this led Ilett et al. to postulate a role of PCP on catecholamine stores – rather than direct receptor agonism – which has since shown to be the case [38]. Interestingly, while the direct effect of arylcyclohexamines in isolation is to increase heart rate and blood pressure, some studies have shown that coadministration of other stimulant drugs, in particular cocaine, may ameliorate the sympathomimetic effects of subsequent arylcyclohexamine use [231], further complicating the clinical presentation of those intoxicated with these drugs. Since then, the effects of PCP and ketamine on the cardiovascular system have been well characterized, displaying modest rises in heart rate and blood pressure at usual recreational doses [232–235]; in one case series, the mean heart rate and blood pressure in PCP intoxicants were 101 bpm and 146/87 mmHg, respectively [235].

It should be noted, however, that arylcyclohexamines may exert cardiodepressant effects in the critically ill. Commonly overshadowed by the stimulant effects exerted by their effect on catecholamine reuptake inhibition, depletion of catecholamine stores in unwell patients can lead to the unmasking of the intrinsic negative inotropic effect of arylcyclohexamines caused by decreased intracellular calcium availability [231, 236–238].

In contrast to PCP and ketamine, MXE is associated with significantly greater cardiovascular pressor effects. In 2012, the first analytically confirmed case series of methoxetamine use provided confirmatory data of these effects [70]. Three individuals from London – two of whom had used only methoxetamine – were found to have tachycardia ranging from 113 to 135 bpm and to be hypertensive (systolic BP 187–201 mmHg, diastolic BP 78–104 mmHg); their serum MXE concentrations were 0.09, 0.12, and 0.20 mg/L. A second case series of three individuals from York also presented with mild cardiovascular stimulation [69]. Interestingly, though the observed effects were milder than those observed in the London group (heart rate 67–107 bpm, systolic

BP 148–194 mmHg, and diastolic BP 104–112 mmHg), their blood MXE concentrations were generally higher (0.16, 0.24, and 0.45 mg/L).

Other Cardiovascular Effects

There is little evidence as to the effects of PCP and ketamine on cardiac rhythm, while there are no data for MXE. Further, the paucity of experimental data in this area is somewhat contradictory, with ketamine having been observed to both enhance and diminish adrenaline-induced dysrhythmias in animal models [239–242].

In a series of 233 cases of acute recreational ketamine toxicity, despite palpitations being a common presenting symptom (likely to be related to sinus tachycardia), no cases of significant arrhythmia were recorded [234]; there were also no reports of myocardial infarction. Further supporting this is the considerable experience of ketamine in the setting of cardiac catheterization and as an anesthetic, which have not demonstrated proarrhythmic effects [243, 244].

However, a recent study in rabbits has suggested that chronic use of ketamine may result in remodelling of the myocardium, with ventricular myocardial apoptosis, fibrosis, and increased sympathetic sprouting leading to alteration of underlying cardiac electrophysiological properties and possible arrhythmogenesis [245]. Chronic ketamine use has also been shown in mice studies to cause hypertrophy of cardiac muscle with subsequent lysis and coagulative necrosis, with subsequent ECG tracings showing signs of myocardial ischemia [43].

Effects on the Respiratory System

The introduction of PCP and ketamine as dissociative anesthetic agents was based on the observations that they produced markedly less respiratory depression than traditional anesthetics [3]. In reality, they exhibit mild dose-related respiratory depression [246], though usually only in high or overdose [6, 103, 247]; an animal study using doses of 20 mg/kg of PCP successfully produced respiratory depression. The pattern of

respiratory depression differs from that of other anesthetic agents in that they have no effect on the slope of the CO₂-response curve; however, it shares similarity with opiates in shifting the curve to the right; that is, respiratory response to hypercarbia remains intact [248]. This also suggests that at the high doses required to cause respiratory depression, this action is via opioid and sigma receptors [38, 246]; this is supported by the observation that at sub-anesthetic doses the role of opioid receptor-mediated analgesia is minimal [158].

However, at usual recreational doses, the effect on respiratory depression is minimal, with clinical studies demonstrating maintenance of, or even an increase in, minute ventilation, tidal volume, and respiratory rate [8, 249]. In a review of 1,000 cases of acute PCP intoxication, tachypnea was much more commonly observed than was bradypnea [232]. Protection of airway reflexes and maintenance of airway muscle tone has also been demonstrated [250]. Further, ketamine has been noted to have a bronchodilatory effect, postulated to be via two mechanisms: (1) indirect stimulation of β_2 adrenergic receptors via catecholamine reuptake inhibition and (2) direct anticholinergic effect on bronchial smooth muscle [112, 251].

Arylcyclohexamines increase tracheobronchial mucus gland secretion [112], which may be of significance in overdose in conjunction with the potential for respiratory depression at high doses.

Effects on the Urogenital System

The toxic effects of arylcyclohexamines, and ketamine in particular, on the urogenital system have only been described relatively recently [252–254]. Only one study has investigated the effects of ketamine on the kidney after acute administration; after a 50 mg/kg administration of ketamine, rats demonstrated decreased glomerular filtration rate and renal plasma flow lasting 2 days [255]. Most studies and reports describe the effects of chronic ketamine use on the urogenital system; the following relates to chronic use.

Urogenital toxicity from ketamine displays a dose–frequency relationship, with cessation of use correlating with improvement in symptoms; however, severe fibrotic changes in the bladder are irreversible, and cessation of ketamine only prevents worsening of pathology in those with early bladder effects [256]. Common symptoms of urogenital toxicity include dysuria, hematuria, urinary urgency, urge incontinence, frequency, and nocturia [254]. In self-reported ketamine users, the frequency of lower urinary tract symptoms and cystitis has been documented to be as high as 27.0% and 32.0%, respectively [178, 254]. The mechanism of urogenital toxicity is unknown. However, it is clear that the lower urinary tract is more commonly affected, with the upper urinary tract usually affected after only more prolonged ketamine use.

It is thought that ketamine in particular, and its metabolites, may be directly toxic to the mucosa of the lower urinary tract, owing to their accumulation in urine. This may be due to effects on the microvasculature leading to ischemia and fibrosis [252, 253].

Bladder Effects

The first stage of effects on the bladder is stasis, resulting from a functional disturbance caused by infiltration of mononuclear cells into the bladder and the kidney, with a resultant increase in the risk of infection [257]. The second stage shows degeneration of nerves and the neuromuscular junction, with subsequent muscle thinning. In the third stage, bladder muscle degeneration is distinct, with replacement by fibrous tissue. The resulting small and rigid bladder causes frequent voiding [43], with bladder volumes reported to be as low as 30–100 mL in severe cases [252]. Bladder biopsies taken from chronic ketamine users have shown chronic inflammatory changes similar to those seen with other forms of interstitial cystitis [253, 258].

MXE was initially marketed as a “bladder friendly” alternative to ketamine. While there have been no human case reports of bladder or renal toxicity with methoxetamine use, animal models have shown that methoxetamine does cause inflammatory changes and fibrosis in the

bladder and both tubular and glomerular changes in the kidney, which are comparable to those in similar animal models of chronic ketamine administration [259].

Renal Effects

There is evidence that ketamine causes interstitial changes in the ureters and kidneys similar to those seen in the bladder, with mononuclear cell infiltration in the kidneys seen after between 1 and 3 months of ketamine treatment in mice [260]. It is unclear at this stage whether these chronic changes lead to ureteric or kidney tumors [261].

Hydroureter and hydronephrosis are reported in up to half of chronic users presenting with lower urinary tract symptoms [252]. In some of these cases, this was found to be due to renal papillary necrosis, with sloughing of the papilla into the ureter causing ureteric obstruction. In the majority of cases, however, proximal dilatation of the urinary tract is likely to be a result of the bladder changes described above.

There has been one case report in the literature of ketamine-induced renal infarction in an otherwise healthy 20-year-old female, who had presented with persisting left flank pain for 3 weeks [262]. It is thought that decreased nitric oxide synthesis might be the mechanism in this case, with vasospasm from decreased nitric oxide leading to hypoperfusion and subsequent infarction.

Effects on the Gastrointestinal System

There is little published on gastrointestinal (GI) effects of the arylcyclohexamines. User reports have described nausea, vomiting, and abdominal pain with ketamine use; however, there is no description of GI symptoms associated with use of PCP, MXE, or 3-/4-MeO-PCP in the major published case series [70, 101, 232, 235]. An early report of prominent GI symptoms with PCP use was thought to be due to the presence of a contaminant [263].

Users' reports of ketamine have commonly described nausea, vomiting, and abdominal cramps ("K-cramps"); however, there is limited

data on the frequency of these symptoms. In a study of ketamine users from the UK, the incidence of nausea was as high as 42.2%, while K-cramps were the most common reason for frequent users to seek medical attention [180]. In the largest case series of ketamine use, the incidence of abdominal pain and nausea was found to be 21% and 9.9%, respectively [234]. This study also noted abnormal liver function tests and/or dilatation of the common bile duct in 16.3% and 5.7% of users, respectively. In another case series, 12 of 14 users (85.7%) with GI symptoms who had an endoscopy performed were found to have gastritis [264]. While the pathophysiology of these effects is not characterized, improvement in GI symptoms was noted on follow-up after abstinence from ketamine use [264, 265]. A recent online survey advertised at clubs, festivals, underground raves, and on social media found 25.3% of 506 Spanish respondents to have experienced "frequent" abdominal pain [178].

Clinical Presentation and Life-Threatening Complications

The toxidrome of acute arylcyclohexamine toxicity has been described as including violent behavior and/or agitation, nystagmus, hypertension, tachycardia, and analgesia [266], and these are certainly their most common acute effects (see Table 7 for most common effects). Their toxidrome is not, however, specific, and therefore discerning these patients from users of other recreational substances can be difficult not only because of the varied effects of the arylcyclohexamines but also due to their rare use in isolation [3, 14, 48, 235]. Further, variation in dose, routes of administration, and even purity of the drug makes true description of a "typical" presentation impossible. PCP and ketamine have also been known to be adulterants to other drugs, such as MDMA, cocaine, and even cannabis [3, 14], while MXE may be confused by both dealers and users for its weaker parent drug ketamine [69].

The most serious of effects appear to be neurological, including seizures and coma, while

Table 7 Frequency of signs and symptoms of arylcyclohexamine toxicity (%)

	PCP [232, 235]	Ketamine [234]	MXE [48, 85]

^aClassic triad of PCP intoxication, first described by Burns et al. [35]

^bAdditional effect included in toxidrome of arylcyclohexamine use (plus analgesia) described by Bey et al. [266]

–No data/not reported

reports of cardiac arrest have also been noted with PCP use. All have been associated with mortality, and this is discussed further below.

Typical doses of arylcyclohexamines for recreational use are shown in Table 8; ketamine, in particular, has a wide therapeutic index. Its doses can be compared to its therapeutic use, where an intravenous dose of 1–2 mg/kg (4–10 mg/kg i.m.) is usually sufficient to induce anesthesia and 0.2–0.75 mg/kg i.v. (2–4 mg/kg i.m.) provides sedation and analgesia [267].

Phencyclidine

The first classification of PCP intoxication was proposed by Burns et al. in 1975, who described three progressive stages that were associated with increasing dose (Table 9) [35]. It was here that a “diagnostic” triad of nystagmus with

hypertension in an agitated, or comatose, patient was first described. Limitations of their categorization included a small sample size of 55 patients, in whom only 10 had confirmatory analysis of PCP use by detection in urine. The route of ingestion was also different between categories – inhalation or insufflation for low and moderate doses and oral for high doses – although it is also important to note that the high-dose category consisted of only one patient from their cohort combined with data from four additional case reports [35]. In 1979, Rappolt et al. drew from their clinical experience of 250 cases to elaborate upon Burns et al.’s work, proposing treatment for the differing stages of PCP intoxication [10].

The largest clinical case series of PCP intoxication was published by McCarron et al. in 1981 and described 1,000 patient episodes [232]. Of these 1,000 episodes, 59.7% were due to PCP ingestion only; the most common co-ingestants

Table 8 Typical recreational doses of arylcyclohexamines, by route of use

	PCP [115]	Ketamine [48]	Methoxetamine [48]
Oral	2–6 mg	75–300 mg	20–60 mg
Insufflation		30–75 mg	40–60 mg
Smoked	1.5–3.5 mg (typical PCP-laced cigarette contains 1–10 mg)		
IM		25–50 mg	15–30 mg
IV	5–10 mg [73]	100–200 mg [73]	5–40 mg [68]

Table 9 Clinical categorization of acute PCP toxicity, adapted from Burns et al. and Rappolt et al. [10, 35]

Stage	Dose (mg)	Serum PCP concentration (ng/mL)	Features		Time to recovery (hours)
			Specific	Common to all Stages	
I: Low dose	<10	25–90	“Behavioral toxicity”: agitation, excitement, incoordination Analgesia/dissociation of somatic sensation	Nystagmus, tachypnea, tachycardia, hypertension (common across all stages of intoxication)	4–8
II: Moderate dose	10–20	90–300	Light coma, or stupor		8–24
III: High dose	>100	>300	Prolonged coma		48–96

were alcohol (55.3%) and cannabis (37.5%). Most (72%) had smoked PCP – either by lacing cannabis or mint leaves with the powder or by soaking cigarettes in liquid – 13% had either snorted or sniffed PCP, 12% had ingested it orally, and 1.6% had injected it intravenously; the remainder had used either multiple routes or had been exposed to accidental inhalation of fumes following a laboratory explosion.

McCarron et al. noted the difficulty in correlating the signs and symptoms of PCP intoxication with the ingested dose; in particular, they acknowledged difficulty both in the accurate determination of the dose taken and the timely receipt of serum concentrations [268]. A later quantitative study by Walberg et al. did not show any significant correlation between serum PCP concentrations and degree of intoxication with PCP [269].

From their case series, McCarron et al. proposed a clinical classification of PCP intoxication based on patients’ sensorium and behavior and described four major and five minor patterns of intoxication (Table 10)

[268]. These patterns of intoxication were not mutually exclusive, and the authors found that patients often transitioned through more than one pattern during their clinical course. Patients with one of the major patterns of intoxication were more likely to require hospitalization, while those with minor syndromes could be expected to improve more rapidly.

Since then, there has been a paucity of large case series of acute PCP intoxication. However, the most recent case series by Dominici et al. [235] showed similar trends to those observed by McCarron et al. three-and-a-half decades earlier. The most common route of administration was still smoking, in 83.2% of the 184 patients reviewed from June 2011 to March 2013. Two-thirds of patients were male, with a mean age of 32.5 years, and more than half (53.8%) had co-ingested at least one additional substance, the most common being cannabis and benzodiazepines (see Table 11).

Overall, the most common clinical findings were nystagmus (57.4–64.1% of patients) and hypertension (47.0–57.0% in McCarron et al.,

Table 10 McCarron clinical classification of PCP intoxication [268]

		Definition/features	Frequency (%) ^{a b}
Major patterns	Coma	Loss of consciousness with no response to verbal or tactile stimuli	9.2
	Catatonic syndrome	Motor signs (posturing, catalepsy, rigidity), psychosocial withdrawal (mutism, staring, negativism), excitement (nudism, impulsiveness, agitation, violence), stupor	14.6
	Toxic psychosis	Hallucinations and/or delusions, with or without acute brain syndrome, but without signs of catatonic syndrome	16.8
	Acute brain syndrome	Disorientation, with any combination of confusion, impaired judgment, inappropriate affect, or recent memory loss	26.6
Minor Patterns	Lethargy/stupor		2.3
	Bizarre behavior		10.6
	Violent behavior		9.7
	Agitation		3.5
	Euphoria		3.0

^aIn those with lone PCP ingestion ($n = 597$); an additional 3.7% were asymptomatic

^bFrequency of most patterns of intoxication was similar between those with lone PCP ingestion and those who had also ingested other drugs. Catatonic syndrome was more common in lone PCP use (7.4% in those with other ingestions), while violent behavior and agitation were more common in polydrug use (14.1% and 7.4%, respectively)

Table 11 Co-ingestions in patients presenting with acute arylcyclohexamine toxicity (%)

	PCP [235]	Ketamine [234]	MXE [85]	3-/4-MeO-PCP [101]
Lone use	46.2	72.2	80.9	11.9

^aDetection of drug reported, but no data provided

^bDetection of drug not reported

systolic BP >140 mmHg or diastolic BP >90 mmHg; not defined in Dominici et al.). Tachycardia (heart rate >100 bpm) was seen in 30% of cases in McCarron et al.'s series; however, it was reported that heart rates greater than 120 bpm were unusual, with the highest heart rate recorded being 140 bpm. Interestingly, the series from Dominici reported only two cases (1.1%) of tachycardia; however, they did not report their definition of this.

Agitated behavior was reported in just over one-third of PCP-intoxicated patients [205,

235]. Between 45.9 and 78.3% of PCP-intoxicated patients were alert at the time of their presentation to emergency services, one-quarter of whom were found to have retrograde amnesia – 11 of these 46 had co-ingested benzodiazepines [235]. Coma was seen in 106 (10.6%) cases involving PCP intoxication, with the typical history featuring sudden onset of violent or bizarre behavior, or what McCarron et al. termed “acute brain syndrome” (see Table 10), followed by, an occasionally abrupt, loss of consciousness [268]. Coma was

differentiated by length of unconsciousness into mild (<2 h), moderate (2–24 h), or severe (>24 h); 55 of those with coma had lone PCP ingestion, of whom 26 (47.3%) were classified as mild, 17 (30.9%) moderate, and 12 (21.8%) severe. Other neuromuscular effects seen with PCP intoxication were generalized tonic-clonic seizures (3.1%), posturing (2.8%), dystonic reactions (2.4%), tardive dyskinesia (1.7%), athetosis (1.3%), and catalepsy (1.3%) [232]. Muscle spasms mimicking extrapyramidal features were seen in 5.9% of cases, none of whom were known to have received neuroleptic medications prior to onset of the dystonic reactions; in 80% of these cases, PCP was the only drug ingested [232].

In McCarron et al.'s case series, tachypnea (respiratory rate >30 breaths per minute) was recorded in 4% of cases; conversely, apnea occurred in 28 patients (2.8%), of whom three displayed Cheyne–Stokes respirations and three suffered respiratory arrest. In 17 of the 28 episodes, apnea was associated with a generalized tonic-clonic seizure. The effects of PCP on respiration were not specifically reported by Dominici et al.

Hyperthermia (temperature >38.9 °C) was seen in 26 patients (2.6%) with acute PCP intoxication; 20 of these were lone PCP ingestion, while no details of the co-ingestants in the other 6 patients were provided [232]. Hypothermia was also reported in 64 patients (6.4%); 41 had co-ingested another drug, but these were not specified. Further, their definition of hypothermia was a temperature <36.6 °C, while no further breakdown of the clinical data was provided [234, 270].

The autonomic effects reported were diaphoresis (3.9%), bronchospasm (2.1%), urinary retention (2.4%), miosis or mydriasis (2.1% and 6.2%, respectively), hypersalivation (1.7%), and bronchorrhea (0.6%).

Ketamine

A case series of 116 presentations associated with ketamine use found similar rates of hypertension (38.8%; systolic blood pressure \geq 140 mmHg)

and tachycardia (29.3%; heart rate \geq 100 bpm) to those seen with PCP intoxication [271]; however, only 13 of these were due to lone ketamine use.

Data from Hong Kong, where ketamine remains the most abused psychotropic drug, has provided the largest case series, of 233 patients, with acute ketamine toxicity [234]. In this series from July 2005 to June 2008, twice as many males as females – with a median age of 22 years – presented to an emergency department after nasal insufflation (88%) or oral (5%) use of ketamine (unknown route of ingestion in 7%). Of those in whom toxicological screening was performed (126 of 233 patients), 72% of samples were positive only for ketamine; the most commonly co-ingested drugs were alcohol (10.3%), ecstasy (6.4%), and methamphetamine (6.0%).

As for PCP, the majority (54.5%) of patients presenting to emergency services after acute ketamine use were alert. However, the most common symptom reported in this cohort was still impaired consciousness (45.5%), although only 14.0% had a recorded GCS of less than 15 on examination in hospital. The most common clinical signs were hypertension (4%; not defined) and tachycardia (39%; heart rate >100 bpm). Forty-nine patients (21.0%) reported abdominal pain, 23 (9.9%) had nausea or vomiting, and 20 (8.6%) reported dysuria; on examination, 41 (17.6%) had abdominal tenderness and 32 (13.7%) were recorded to be hyperthermic (not defined). As mentioned previously, abnormal LFTs (16.3%) and dilatation of the CBD (5.7%) were observed among ketamine users, and while these both demonstrated improvement upon cessation of ketamine use, their significance is uncertain [234, 265]; gastritis appeared to have a similar temporal association with ketamine use in a subgroup of 14 ketamine users who underwent endoscopy [264].

In 96 cases of chronic ketamine use from Hong Kong, the most common features on presentation to outpatient clinics were of cystitis (91.7%) – such as dysuria, urgency, and frequency – while 63 (65.5%) reported chronic abdominal pain, and 15 (15.6%) had psychiatric concerns (not further defined) [272].

Methoxetamine

While no animal or human studies have examined the toxicity of MXE, limited data is available from three small series of acute MXE intoxication, two case series of user reports of MXE use, and data from the EMCDDA–Europol Joint Report on MXE and the NPIS [48, 69, 70, 85, 114, 270, 273]. In one report, males accounted for three times as many users as females, with an overall median age of 24 years [85]. It was most commonly taken by nasal insufflation (37%) or orally (38%) – either by “bombing” or dissolved in water – other routes included i.m. or i.v. injection (total 7%), sublingually, or rectally [270].

A total of 110 nonfatal intoxications and 20 deaths have been associated with MXE use. Collectively, the data suggest that the clinical toxicity of MXE is akin to that of PCP and of ketamine. The first report in the literature of MXE use was published in 2011 [67]. A 32-year-old male was brought to the emergency department after he was found by police and paramedics to be agitated; he had used an unknown amount of MXE by i.m. injection and denied any co-ingestion. On arrival, he had a heart rate of 105 bpm, blood pressure of 140/95 mmHg, respiratory rate of 16, temperature of 37.2 °C, and pupils of 6 mm. He intermittently appeared in a dissociated state and was noted to have rotary nystagmus; the remainder of his neurological examination was normal, and he returned to his baseline mental status after 8 h [67].

Initial reports suggested that the cardiovascular pressor effects of MXE were greater than those of either PCP or ketamine [70, 274]; however, the incidence of hypertension and tachycardia appears to be comparative based on the limited data available [48, 85]. Data from case reports are mixed. One male, presenting within half an hour of i.v. injection of an unknown dose of MXE, was both hypertensive (168/77 mmHg) and tachycardic (134 bpm), and his serum was positive for MXE; however, this was not quantified [68]. Another male who presented agitated and aggressive was tachycardic (120 bpm) but had a normal blood pressure (130/80 mmHg), while a third was hypertensive (167/110 mmHg) with a

heart rate in the normal range (not reported) [275, 276]. In the case presenting with tachycardia, serum MXE concentration was 0.27 mg/L [275]; blood samples were not taken in the hypertensive case. GI symptoms of nausea and vomiting have also been described in user reports; however, no data is available on their frequency [114, 277].

In those with objective recording of conscious state, MXE caused almost double the number of those with impaired conscious state (27.3%) as compared to ketamine (14.0%) [48, 85]. Two reports have associated seizures with MXE use (see section “[Life-Threatening Complications](#)”, below) [85, 278], while other common neurological features of MXE toxicity include agitation in around one-third of users – similar to the rate seen with PCP use – and muscular symptoms in up to 18% of cases [270]. In contrast to PCP and ketamine, a case series of three MXE users reported significant cerebellar toxicity, with their serum MXE concentrations being 0.16, 0.24, and 0.45 mg/L [69].

Methoxylated Arylcyclohexamines

The only case series of other arylcyclohexamine analogues comes from the Swedish STRIDA project, which reported 59 cases of acute 3- and 4-MeO-PCP toxicity [101]; 86.4% were male and the median age was 26 years. Fourteen cases described route of administration: oral was the most common (9 cases; 64.3%), while nasal, i.v., and rectal routes were also reported. As with the other arylcyclohexamines, polydrug use was common. Additional substances were detected in the majority of cases (52 of 59; 88.1%), the most common being cannabis and ethanol (see Table 11); all 7 of the single-substance cases involved 3-MeO-PCP.

The most frequent clinical signs observed with methoxylated arylcyclohexamine use were akin to those observed with PCP, ketamine, and MXE use (see Table 7); altered conscious state (57.6%), tachycardia (54.2%), and hypertension (45.8%) are the most commonly reported, while nystagmus was seen in 30.5% of cases. In the 7 cases of lone 3-MeO-PCP use, there was a greater

incidence of hypertension (100%; systolic BP ≥ 140 mmHg) and tachycardia (71%; heart rate ≥ 100 bpm), with similar rates of altered conscious state (57.1%) and nystagmus (28.6%) [101]. There were no reports of seizures or of altered thermoregulation associated with lone 3-MeO-PCP use.

Emergence Phenomena and the “K- and M- Holes”

The emergence phenomena observed during the recovery phase of anesthesia with arylcyclohexamines has limited their clinical use and was one of the main reasons that PCP was withdrawn less than 10 years after being introduced [9]. Characterized by a confusional state, vivid dreams, and hallucinations, these reactions occurred most frequently in middle-aged males, with an incidence of 17–30% with use of PCP in clinical anesthesia [38]. Following ketamine anesthesia, studies have shown varying incidences of emergence phenomena, from less than 5% to more than 30% of subjects [279–284]. Collectively, the experiences of recreational users during their dissociated state have been commonly referred to as the “K-Hole” and “M-Hole” when associated with ketamine and methoxetamine use, respectively [114, 285]. Other descriptions have included a sensation of feeling light, body distortion, experiences of cosmic oneness, and out-of-body and near-death experiences [103, 286].

The underlying mechanism of the emergence phenomena caused by arylcyclohexamines appears to be due to their depressive effects on visual and auditory relay nuclei in the medial geniculate and inferior colliculus, respectively, leading to misperception and/or misinterpretation of visual and auditory stimuli [287, 288]. Further, the loss of proprioceptive sensation results in decreased sensitivity to gravity, providing an explanation for the out-of-body and floating experiences described by recreational users and by those recovering from general anesthesia [76, 114, 286, 289].

In McCarron’s study of 1,000 cases of PCP intoxication, the incidence of emergence patterns

was described for each category of coma [268]. A total of 106 cases of coma were described, of whom 55 (51.8%) had only ingested PCP; of these, 26 (47.3%) were classified as mild, 17 (30.9%) as moderate, and 12 (21.8%) as severe coma. In the 12 patients with severe coma (>24 h) due to lone PCP intoxication, the emergence patterns included five with acute brain syndrome (defined by McCarron et al. as “disorientation with any combination of confusion, lack of judgment, inappropriate affect, or loss of recent memory (with or without bizarre behavior, violence, or agitation)”) (see Table 10) lasting up to 7 days, one with stupor for 10 days, one with catatonia lasting 3 days, one with lethargy for 24 h, three with agitation, and one with psychosis requiring transfer to a psychiatric hospital. In those emerging from moderate coma, eight developed acute brain syndrome for up to 8 days, three were agitated for up to 14 days, one was psychotic for 7 days, and one displayed bizarre behavior for 4 days; only 4 of the 17 (23.5%) were mentally clear on awakening from coma. For those with mild coma, a majority (14, 53.8%) displayed acute brain syndrome, which lasted less than 24 h in all cases; four were stuporous; two were agitated; two were psychotic for 34 h and 3 days, respectively; one was catatonic; and one displayed violent behavior. Two (7.7%) displayed mental clarity on emergence from coma [268].

Aside from this case series by McCarron et al., there is no other data on the incidence or severity of emergence reactions following acute toxicity and coma associated with PCP or other arylcyclohexamine analogues. The availability of pharmaceutical non-racemic ketamine and reports of its recreational use [290], in particular the S(+)-enantiomer, may impact the prevalence of emergence reactions given the evidence supporting a decrease in the incidence of these reactions with its use, as compared with racemic or R(–)-ketamine [106–108].

Life-Threatening Complications

Massive overdoses, of up to 1 g orally of PCP, have resulted in coma for up to 5 days’ duration [115]. McCarron et al. found that, of those with

coma, almost one-quarter had prolonged, or “severe,” coma lasting more than 24 h, with the possibility of delayed and prolonged hypoventilation and apnea as a result [268]. Burns et al. also noted that such cases were marked by sustained hypertension, tachycardia, and more prominent neurological features, including seizures [291, 292]. These findings were consistent with McCarron et al.’s results demonstrating increased frequency of almost all clinical features of PCP intoxication with increased duration of coma – with the exception of nystagmus and hypertension, which were uniformly present in around 60% and 50% of all PCP intoxicants, respectively, regardless of duration of coma [268].

There is conflicting data regarding the association between serum PCP concentration and clinical findings. Most demonstrate no correlation between the two, with the exception of the finding of a moderate correlation ($r = 0.60$, $p < 0.05$) between plasma PCP concentration and hypertension in a series of 5 patients with acute PCP toxicity [293]. It was also noted in the series by Walberg et al. that, of the 183 patients whose blood tested positive for PCP, all 14 of those with coma had uniformly higher serum PCP concentrations (>0.1 mg/L) [269]. One explanation for the lack of association is the high protein- and tissue-bound fraction of PCP, meaning blood PCP concentrations do not reflect total body load [293, 294]. There is also some evidence to suggest that chronic users develop tolerance to PCP, and, as a result, their toxic blood concentrations are significantly higher than for casual users [295, 296].

In the largest case series of 1,000 acute PCP intoxications, there were three cases of cardiac arrest, all of whom were successfully resuscitated; however, no further details were provided [232]. One additional patient died post-cardiac arrest, found on autopsy to be due to pulmonary embolism. Three patients suffered respiratory arrest, from a total of 28 in whom apneas were noted; 16 (57.1%) had co-ingested a sedative—hypnotic or narcotic drug in addition to PCP. Of the 28 in whom apneic episodes were seen, 17 were associated with seizures, with some requiring intubation and ventilation for prolonged

apnea; it was not reported how many of those who had seizures had also co-ingested other substances. A total of 26 patients suffered from one or more generalized tonic–clonic seizures, while a further 5 patients had status epilepticus; in all cases, status epilepticus was terminated by administration of intravenous diazepam [232]. Two cases of seizure have been reported with MXE use: one had multiple seizures terminated by administration of i.v. clonazepam, after inhaling the vapor of 50 mg of MXE powder over a couple of minutes – his serum MXE concentration was 0.03 mg/L [278]; a further case is mentioned in a series of MXE intoxications, but no further details were reported [85].

Rhabdomyolysis (creatinine phosphokinase [CK] $>16,000$ IU/L) was seen in 2.5% of 1,000 patients with PCP intoxication; of these, 40% had acute kidney injury (defined as one of (a) rising serum creatinine or urea despite i.v. rehydration, (b) serum urea/creatinine ratio between 9 and 11, or (c) oliguria [urine output <500 mL day] persisting for several days) [297].

The vast majority of patients with acute arylcyclohexamine intoxication will survive with supportive care. However, it is the group that is particularly behaviorally disturbed in whom additional significant harm can occur and who can pose a significant management challenge requiring critical care admission. Owing to the dissociative and analgesic effects in combination with acute behavioral disturbance and agitation, patients may self-inflict significant damage while under the influence of arylcyclohexamines; cases as marked as nuclear evisceration and genital mutilation have been reported [298–300].

Other Considerations

A concern with regard to the potential for serious toxicity and/or mortality associated with recreational arylcyclohexamine use is the prevalence of their misrepresentation, either intentionally or accidentally, as a contaminant. Historically, PCP has a long history of this. Early in its use, it was often found to be adulterated by, or an adulterant of, other arylcyclohexamines. While some were

thought to be less potent than PCP, others with increased potency, such as TCP, PCE, and PCPy, had the potential to cause significant inadvertent toxicity. The precursor to, and sometime contaminant of, PCP – PCC – was reported to cause serious toxicity, including coma and death; however, there is little further detail about its clinical effects [3, 62, 64].

More recently, there have been reports of ketamine and MXE being interchanged for each other. Given the binding affinity of MXE for the NMDA receptor is significantly higher than that of ketamine [127], there is the potential for inadvertent overdose. With the marketing of MXE as an “alternate” form of ketamine, the risk of significant toxicity with the use of MXE by those inexperienced in its dosing is compounded by its longer time to onset than ketamine, of up to 90 min, which has caused some users to prematurely re-dose [114].

Further, there are reports of ketamine being sold on the street in its non-racemic form. Given the S(+)-enantiomer is four times more potent in its dissociative effects than its R(–)-enantiomer, this presents further risk to those not aware of the difference in effects between racemic and non-racemic mixtures [40].

Deaths

Throughout its decades of use, PCP has been associated with hundreds of deaths. This is, however, more commonly due to the acute behavioral disturbances associated with mild intoxication [35, 115, 301]. After significant PCP ingestion, coma is protective from potential self-harm in these patients, while risk of death from accidental overdose is minimized by provision of adequate supportive care.

Data from a recent 5-year retrospective review from the New York City Medical Examiner’s Office documented a total of 138 autopsy cases, from 2003 to 2007, in which PCP was detected in postmortem blood samples [296]. Of these, the majority (80; 58.0%) were involved in violent deaths in which PCP was detected but not thought to be directly related to the cause of death;

52 (37.7%) were deemed to be as a result of mixed drug intoxication, 5 (3.6%) were nonviolent deaths in which only PCP was detected, and in one (0.7%), the cause of death was indeterminate.

Previous case reports have reported lethal serum PCP concentrations of greater than 2.0–2.5 mg/L [302]. However since then, deaths have been reported where the serum PCP concentration was much lower. In one case, a 30-year-old man without any medical comorbidities died from a nonviolent cause [296]. Urine toxicology screen on presentation to the emergency room was positive only for cannabinoids, and serum was negative for ethanol, paracetamol, and salicylates; serum PCP concentration at autopsy was 0.07 mg/L; however, this was 5 days after his initial presentation. A quantitative study by Walberg et al. did not show any significant correlation between serum PCP levels and degree of intoxication with PCP [269]. However, of the 183 patients whose blood was positive for PCP, all of those with coma had a serum PCP level greater than 0.1 mg/L. Indeed, significantly raised serum PCP concentrations are usually seen after massive overdose resulting in death attributable to PCP toxicity, rather than consequences of behavioral disturbance. A serum PCP concentration of 7.0 mg/L was reported in a case of status epilepticus with resultant cardiopulmonary arrest and death [115, 303].

Ketamine

Despite its widespread use, there is little recent data on the number of deaths relating to ketamine use. The first documented blood ketamine concentration in a fatality was reported in 1988, in a 31-year-old female who died after an accidental injection (not reported whether i.v. or i.m.) of up to 900 mg of ketamine; she had a blood ketamine concentration of 7.0 mg/L [304]. A comparison case also detailed in this report, of a 46-year-old man given 100 mg of ketamine (route of administration not documented) during anesthesia for surgery post-gunshot wound, showed a postmortem blood ketamine level of 3.0 mg/L. He suffered

cardiac arrest and was pronounced dead 40 min after receiving ketamine; the final cause of death was not reported. A review by the authors of 27 other cases in which ketamine was detected postmortem over a period of 2 years showed blood concentrations of between 0.1 and 9.5 mg/L, in which 15 were less than 1.0 mg/L [304]. No comment was made about the cause of death in these 27 cases or whether other drugs or alcohol were detected; however, their report highlights the issue of timing of postmortem blood and tissue samples and the importance of considering the time of death in interpreting these results.

A review of ketamine-associated deaths examined at the New York City Office of the Chief Medical Examiner between 1997 and 1999 identified 12 nonhospital deaths due to acute intoxication, none of which were due solely to ketamine [305]; of the 87 total ketamine-associated deaths, the vast majority, 72, were inhospital deaths in the setting of treatment with ketamine for burns or surgery.

In 2008, Schifano et al. presented data on 23 ketamine-associated deaths in the UK from 1993 to 2006; of these, only four cases were identified in which ketamine was the only drug found, three of which were deemed to be accidental overdoses, with the other being a case of suicide [306, 307]. Ketamine concentrations were not reported in these cases. Since then, data from the UK's National Programme on Substance Abuse Deaths (NPSAD) showed a peak of 23 deaths related to ketamine use in 2009, with a subsequent decline to 12 and 8 deaths in 2011 and 2012, respectively [308]. A total of 93 deaths in which ketamine was mentioned on the death certificate were identified from the NPSAD database; in most (70; 75.3%), other drugs and/or alcohol were also detected [40]. In the remaining 23 cases, where ketamine was the only substance detected, it was not possible to determine whether ketamine was the actual cause of death [40].

Reports of lone ketamine toxicity leading to fatality have reported blood ketamine concentrations varying from 1.8 to 27.4 mg/L [304, 309, 310], while previous studies in squirrel monkeys investigating anesthetic and lethal ketamine doses have led to the estimate of a lethal i.v. dose in

humans of 11.3 mg/kg [307, 311]. In comparison, anesthetic studies have demonstrated that i.v. loading doses of 2 mg/kg of ketamine, followed by continuous ketamine infusion, were able to achieve a targeted blood ketamine concentration of between 2 and 3 mg/L, which maintained stable anesthesia [312, 313]. Subjects were found to be rousable to deep stimulus at blood ketamine concentrations of between 1.0 and 1.5 mg/L, while recovery from anesthesia was seen at blood ketamine concentrations between 0.50 and 0.64 mg/L [312–315]. Apart from the limited case reports of fatalities documenting blood ketamine concentrations, there are no other published data for ketamine concentrations in recreational use or overdose.

Methoxetamine

In 2012, no confirmed deaths were attributable solely to the use of MXE [75]. By 2014, 20 deaths associated with MXE use had been reported to the EMCDDA [48, 116]; in 8 cases, MXE was the only psychoactive substance reported. Of those reporting a cause of death, four cases listed MXE in the cause of death, 2 cases were due to mixed overdose, while three cases listed MXE as contributing to death [48]. Interestingly, 4 of the 20 deaths were from drowning, perhaps highlighting the theoretically increased potential for accidental self-harm with MXE given its prominent cerebellar toxicity alongside the dissociation associated with other arylcyclohexamines [69]. Postmortem MXE concentrations in blood were highly variable, ranging from 0.03 mg/L (cause of death: mixed overdose) to 5.2 mg/L (cause of death: drowning) [48, 72, 316]; there was overlap in MXE concentrations with acute toxicity, which in one case series ranged from 0.16 to 0.45 mg/L [69].

The first case report of death involving MXE, published in 2013, was that of a 26-year-old male found deceased in his home, whose postmortem blood MXE concentration was 8.6 mg/kg; three synthetic cannabinoids were also detected (concentrations not reported), as was tetrahydrocannabinol [71]. A year later, a case of death where

clinical features were recorded was reported from Poland [73]. A 31-year-old man presented to the emergency department in deep coma; he was tachycardic (heart rate 120–140 bpm) and hyperthermic (temperature 39 °C) and had rhabdomyolysis with a peak CK of 220,531 IU/L. He was also reported to have had seizures, required mechanical ventilation for respiratory failure, and developed acute liver and renal failure; he was admitted to intensive care but died 28 days after his presentation. Serum MXE concentration taken 8.5 h after presentation was 0.32 mg/L; amphetamine was also detected (0.06 mg/L). The first report of fatality from lone MXE use was also reported from Poland, in 2015, of a 29-year-old man who was found deceased in his home [73]; his estimated serum MXE concentration was 5.8 mg/L.

Diagnosis

Clinical

As with all patients who present with recreational drug overdose, collateral history where available provides important information about the dose and route of exposure, co-ingestant(s), and previous drug use. The most common clinical signs in arylcyclohexamine intoxication are nystagmus and hypertension; in the presence of an altered sensorium – either agitation or coma – these patients have been described to have a classic triad of PCP intoxication.

Serum and Urine Arylcyclohexamine Testing

Testing for arylcyclohexamines is not part of routine toxicological screening, and samples are often required to be sent to specialist laboratories for their identification.

Phencyclidine can be qualitatively detected using enzyme-linked immunoassay techniques with a sensitivity of 0.01 mg/L; however, false-positive results are possible due to cross-reactivity with molecularly similar substances such as

dextromethorphan [38]. No commercially available immunoassay exists for ketamine; its detection is by gas chromatography and mass spectroscopy. Rapid-detection urine assays have recently been developed and are reported to be sensitive and specific, with a limit of detection of 0.005 mg/L [317, 318]. However, there have been case reports of false-positive results for PCP in those patients also on venlafaxine, with its active metabolite *O*-desmethylvenlafaxine cross-reacting with the PCP assay reagent [319–321]. Other drugs that have been shown to cause false-positive results in urine PCP assays include dextromethorphan and diphenhydramine [322, 323].

Methoxetamine is tested for using either calorimetric or immunoassay kits and analyzed by gas chromatography–mass spectrometry (GC–MS) techniques. Newer techniques for methoxetamine and other arylcyclohexamine analogues have recently been developed, with the use of high-pressure liquid chromatography (HPLC) able to detect these compounds in both blood and urine [324]. With the rapid appearance of novel arylcyclohexamine analogues, interpretation of immunoassay results must be made with caution. Cross-reactivity between the methoxylated arylcyclohexamines and PCP has been described after confirmatory MS analysis [101].

While toxicological screening for these compounds is not required routinely, it can be useful academically, particularly to help confirm the pattern of toxicity associated with novel arylcyclohexamines. This has been shown in the recent case series of 3- and 4-MeO-PCP as well as the earlier case reports of MXE use [68, 69, 71–73, 101, 275].

Other Investigations

Patients with significant clinical features should have routine hematology and biochemistry testing. Nonspecific laboratory findings include leukocytosis, hypoglycemia, and elevated CK, urea, and creatinine [232, 234]. In the case series of 1,000 patient episodes by McCarron et al., 22% of those tested had hypoglycemia of less than

70 mg/dL (3.9 mmol/L). Creatinine kinase was elevated above 300 IU/L (reference range 5–200 IU/L) in 70% of cases, of whom roughly one-third each were violent, agitated, and calm; the highest recorded CK was 423,045 IU/L [232]. Of those who had no other reason to have an elevated white blood cell count (e.g., trauma, rhabdomyolysis, or infection), 39% were shown to have white blood cell counts of greater than 12,000/ml³. The number of those with leukocytosis (36%) was similar in a case series of acute ketamine toxicity, while raised creatinine kinase was seen in 32% of cases [234]

An ECG is an essential investigation in patients with acute recreational drug toxicity in the critical care setting; however, there are no findings specific to arylcyclohexamine toxicity. In one study of anesthesia during electroconvulsive therapy, ketamine was found to cause QTc prolongation from a mean of 410.9 ms at baseline to a mean of 431.6 ms after induction with a 1 mg/kg bolus [325]; there were no episodes of torsade de pointes, and this is therefore of doubtful clinical significance. Isolated reports of ST-segment and T-wave changes with ketamine use also exist. One case of broad-complex arrhythmia with peaked T-waves in the setting of PCP intoxication was likely caused by hyperkalemia of 9.35 mmol/L rather than arylcyclohexamine-specific effects [326]. There has also been a single case report of transient Brugada syndrome in a 31-year-old Caucasian male who had nasally insufflated ketamine [327]. Resolution of the Brugada pattern and subsequent testing demonstrated no other reason for the ECG findings, and it was determined that ketamine’s inhibition of I_{Na} and I_{Ca} channels was the cause of the ST elevation [327, 328]. Reports of propofol also causing a transient Brugada syndrome with subsequent malignant arrhythmias is of importance due to its use as a sedative agent in the critical care setting, especially when used to sedate patients with recreational drug toxicity [329].

An electroencephalogram (EEG) may be useful in the undifferentiated comatose patient to exclude ongoing seizures or status epilepticus as a cause for unconsciousness or neuromuscular excitation. Findings seen in arylcyclohexamine

Table 12 Differential diagnoses for arylcyclohexamine intoxication

Other intoxicants	Gamma hydroxybutyrate, stimulant drugs, other hallucinogens Anticholinergic drugs Neuroleptic malignancy syndrome Withdrawal syndromes
Mental health disorders	Schizophrenia Acute manic episode, exacerbation of bipolar affective disorder
Metabolic	Hyponatremia Hypoglycemia Hypoxemia Hyperthyroidism
Infective	Sepsis Meningitis/encephalitis
Intracranial pathology	Intracranial hemorrhage

toxicity include diffuse slowing with θ and δ waves, which may return to normal prior to clinical improvement [38, 263, 330, 331].

Differential Diagnoses

The varied signs and symptoms seen with arylcyclohexamine intoxication, and indeed the frequency of co-ingested drugs, make for a wide list of differential diagnoses (Table 12). Arylcyclohexamine intoxication therefore requires a high index of suspicion and gathering of as complete a collateral history as possible.

Management

Conservative and supportive management is the mainstay of treatment in arylcyclohexamine toxicity, with the focus on maintaining a clear airway, adequate respiration, and oxygenation; providing circulatory support where necessary; and being mindful of thermoregulation due to the potentially significant psychomotor agitation and bioamine reuptake inhibition. Restraint and sedation may also be necessary in the most acutely disturbed patients to avoid harm to both the patient and clinical staff tasked with their care; this is described in more detail in the next section. There is no specific antidote for

arylcyclohexamine toxicity, and most patients will survive with purely supportive measures.

Intravenous access is required for all patients who present with significant acute arylcyclohexamine toxicity, with blood taken for electrolytes, glucose, lactate, urea, and creatinine. In the significantly agitated patient, rhabdomyolysis may be a feature, with myoglobin-associated acute kidney injury as a cause of high morbidity and mortality associated with PCP intoxication in particular [332, 333]. When present, it should be treated aggressively with intravenous fluids (see ► Chap. 32, “Toxicant-Induced Rhabdomyolysis”).

Seizures can be treated initially with benzodiazepines. In the setting of status epilepticus, or in a patient with an otherwise compromised airway, sedation with a barbiturate or propofol, paralysis, and endotracheal intubation is indicated. In patients requiring critical care intervention and management, significant hyperthermia is associated with poor prognosis [334–336]. Therefore, particularly in the setting of hyperthermia, prompt anticonvulsant therapy should also be instigated to minimize additional thermogenesis from seizure activity. In those patients with significant hyperpyrexia (>39 – 40 °C), aggressive cooling methods should be employed, including the use of cold intravenous fluids, packing of the axillae/groin with ice, and, if necessary, immersion in an ice water bath or the use of an intravascular cooling device (Grade III recommendation).

Patients should have continuous cardiac monitoring, due to the prevalence of tachycardia and reports of arrhythmias. While hypertension is common, it is usually short-lived, with most cases resolving without the need for specific antihypertensive treatment. Those that require medicating for behavioral disturbance, agitation, or seizures – such as benzodiazepines – are likely to see a beneficial effect of this on blood pressure. In 563 patients with PCP-induced hypertension, only one required specific antihypertensive medication; seven additional patients had known essential hypertension, of whom five received antihypertensives [232]. If hypertension is persistent and severe (systolic BP >200 mmHg or diastolic BP >120 mmHg), we recommend treatment

with intravenous glyceryl trinitrate as its short half-life enables it to be readily titrated (Grade III recommendation). While this is also true of sodium nitroprusside, it has the potential to increase catecholamine secretion and worsen tachycardia [337, 338]. The longer half-lives of calcium channel blockers make them impractical for rapid titration in the critical care setting, while beta-blockers are generally not recommended in the setting of acute stimulant toxicity as they can result in unopposed alpha activity and worsen hypertensive crises.

Agitation and Behavioral Management

As the psychotomimetic features of acute intoxication are similar to those seen in emergence reactions, it is useful to be mindful of the importance of non-pharmacological modalities of treatment in caring for the patient intoxicated with arylcyclohexamines. However, the spectrum of behavioral disturbance is wide. Indeed, the major toxicity of arylcyclohexamines is related to these effects, with unawareness of surroundings and oblivion to pain due to their dissociative and analgesic effects leading to the potential for self-inflicted injuries and extreme overexertion. The potential for accidental self-harm is theoretically exacerbated with MXE given its reported cerebellar toxicity [69].

In mild intoxication, management may involve maintaining an environment of relative sensory deprivation [339]; however, this has not been formally studied (Grade III recommendation). Patients with more severe toxicity and acute behavioral disturbance may initially require physical restraint in order to establish intravenous access to facilitate chemical sedation. Overall, chemical restraint is preferred, as physical restraint may exacerbate underlying rhabdomyolysis. Benzodiazepines are the preferred sedating agent, as antipsychotic medications may exacerbate hyperthermia, lower the seizure threshold, or worsen dystonic and anticholinergic reactions [266].

If an antipsychotic medication is required, atypical agents offer a better choice than

traditional antipsychotics due to their more favorable side effect profile, in particular their less pronounced extrapyramidal side effects [340]. In one series of PCP intoxication, 168 patients received haloperidol and 66 received chlorpromazine for agitated behavior, in whom 10 (6.0%) and one (1.5%), respectively, developed dystonic reactions [268]. There is limited published experience with newer sedatives, such as dexmedetomidine, or newer atypical antipsychotics. In our opinion, therefore, benzodiazepines should remain first line in these patients (Grade III recommendation). Initial intramuscular dosing, using an agent with good systemic absorption by this route such as lorazepam, may be required in those with very severe behavioral disturbance; however, i.v. administration is the route of choice as it allows for more titrated dosing.

Decontamination and Elimination

Activated Charcoal

There are no human studies investigating the role of activated charcoal (AC) administration on arylcyclohexamine toxicity; data on the use of AC is limited to a single study investigating PCP in dogs [341]. Patients with significant arylcyclohexamine toxicity generally have significant behavioral disturbance and/or drowsiness which would limit AC administration and routine use of AC is not recommended.

Urinary Acidification

As the arylcyclohexamines are weak bases, acidification of urine theoretically enhances their elimination; indeed, the use of ammonium chloride was previously advocated for this purpose [342]. However, the risk of inducing systemic acidemia outweighs the potential benefits (Grade III recommendation). Urinary acidification also has the potential to increase the risk of acute tubular necrosis in patients with rhabdomyolysis [333, 343]. Furthermore, while renal clearance of PCP has been shown to be increased by up to 23% following urinary acidification, this accounts for only 1% of total PCP clearance due to the majority of its clearance being via hepatic metabolism

[109, 344]. Given these concerns, coupled with the fact that the majority of patients with arylcyclohexamine intoxication will survive with supportive care, urinary acidification is not recommended.

Hemoperfusion and Hemodialysis

Due to the large volume of distribution of PCP and the other arylcyclohexamines, along with their high lipid solubility, hemodialysis and hemoperfusion are not effective in managing arylcyclohexamine toxicity [345].

Emergence Reactions

As described above, McCarron et al. reported a high incidence of emergence reactions following acute PCP toxicity, with more than 75% of those with moderate or severe coma displaying confused, agitated, or psychotic behavior [268]. In those with mild or moderate coma, only 13.9% emerged from their altered conscious state with clear sensorium, while none of those with severe coma did so.

There are no data for the treatment of emergence reactions following acute arylcyclohexamine toxicity causing coma. Indeed, apart from the study by McCarron et al., there are no data on the frequency of emergence reactions following arylcyclohexamine toxicity in the recreational setting. Anesthetic studies demonstrate that the incidence of emergence phenomena after general anesthesia with PCP and ketamine ranges anywhere from less than 5% to more than 30% [38, 103]. While the incidence of emergence reactions following anesthesia with PCP has been reported to be higher in males [38], it appears to be higher in women after ketamine anesthesia [104, 267, 346].

The role of preanesthetic medication in reducing the incidence and/or severity of emergence reactions following ketamine anesthesia was acknowledged even after its first report; however, it was not investigated at that time [11]. Initial studies investigating various premedications offered conflicting results about the beneficial effect of agents such as droperidol, chlorpromazine, and opiate-containing

regimens [346–351], and these are not recommended [103, 351].

Benzodiazepines have been shown to reduce the incidence of emergence reactions following ketamine anesthesia, with initial studies suggesting lorazepam to be superior to other benzodiazepines, including diazepam (Grade II-I recommendation) [351–353]. However, the introduction of midazolam has since superseded their use due to its shorter half-life and water solubility and has been shown to be superior to diazepam in reducing the incidence of emergence reactions (Grade I recommendation) [354–356]. In one randomized, double-blinded study of those induced to anesthesia using 250 mg i.v. ketamine, only 4% of those who also received 12.5 mg i.v. midazolam had emergence reactions compared to 36% of those who received 20 mg i.v. diazepam in addition to ketamine [355].

While these data provide good evidence of the efficacy of benzodiazepines, and in particular midazolam, for reducing the incidence of emergence phenomena, they must be interpreted with some caution in managing the patient with acute arylcyclohexamine toxicity. Not only are they based on controlled anesthetic studies, most studies administered benzodiazepines as a premedication or at the time of induction of anesthesia, though other studies have suggested that they are equally effective administered at the completion of a procedure [280, 357]. A study by Levänen et al. comparing dexmedetomidine (2.5 µg/kg) with midazolam (0.07 mg/kg) noted a significant reduction in CNS effects in the dexmedetomidine group; however, these were mostly unpleasant dreams, with no reports of agitated or psychotic behavior [358]. A more recent study comparing dexmedetomidine (1 µg/kg) and midazolam (0.02 mg/kg) also demonstrated less subjective CNS effects in the dexmedetomidine group; however, their findings were not significant [359]; similarly, most of the described effects were mild or moderate dream states, without any significant behavioral changes reported.

As an aside, there is also evidence that the S(+)-enantiomer of ketamine is responsible for less emergence phenomena than either the racemic mixture or, in particular, the R(–)-enantiomer

[106–108]. As the S(+)-enantiomer is now available in a pharmaceutical preparation [267], its use would be recommended above the racemic mixture for anesthesia and for sedation in the critical care setting.

Disposition

Most patients with mild intoxication with arylcyclohexamines will be able to be discharged from the emergency department after a period of monitoring that has demonstrated normal cognition, normal and stable vital signs, normal ECG, and normal biochemical markers. Those with persisting signs of mild arylcyclohexamine toxicity or requiring repeat blood tests, and who do not have significant behavioral disturbance, may be managed in an observation unit or with standard ward-based care.

Patients with severe toxicity, as highlighted in Box 1, will require critical care admission for further targeted management as discussed in the sections above.

Special Populations

Dependants

The impact of the behavioral effects of the arylcyclohexamines, including agitation, violence, and altered sensorium, necessitates consideration of the resulting social issues [360–362]. While not specific to arylcyclohexamines, these issues require the assessment and safeguarding of vulnerable adults – and, indeed, children – due to the potential for significant intimate partner domestic abuse, crime, and incarceration [298, 363].

Children

In addition to the potential for ingestion of arylcyclohexamines in either liquid, tablet, or powder forms, significant accidental poisoning, in particular with PCP, can occur from exposure

Box 1

Criteria for critical care management of acute arylcyclohexamine toxicity

Criteria for admission to intensive care unit	Criteria for discharge from intensive care unit
Agitation or violent behavior requiring sedation and/or intensive monitoring	Settled or settling behavior
Rhabdomyolysis, requiring hemodialysis	Maintenance of adequate urine output and improving renal function
Severe, refractory hypertension	
Severe hyperthermia (temperature >39–40 °C)	Thermoregulation not requiring exogenous cooling
Prolonged coma	Improvement in mental status
Status epilepticus or seizures requiring therapy	Resolution of seizures
Other reason(s) for endotracheal intubation	Successful extubation and maintenance of patent airway
Injuries/trauma secondary to behavioral disturbance requiring ICU level care	

to passive smoke [364]. Signs may be as subtle as listlessness and decreased responsiveness to tactile stimuli, irritability, and poor feeding in the very young [365]. Other neurological signs observed in adult presentations may also manifest in children, with nystagmus, ataxia, increased muscle tone, and opisthotonus all reported [364–366]. Hypertension was also common, found in 30% of children in one study, while seizures, respiratory depression, and apnea were reported more frequently than in adults; agitation and violent behavior were less commonly seen [365, 366].

All pediatric patients with acute arylcyclohexamine toxicity require continuous monitoring to observe for any fluctuation in consciousness or cardiorespiratory status [266]. Infants may require longer observation and admission due to case reports of their delayed recovery [364]. Any child who presents after exposure to arylcyclohexamines should have safeguarding procedures enacted.

Pregnant and Breast-Feeding Patients

Phencyclidine has been shown to cross the placenta and is associated with poor feeding, irritability, and hypertonicity in neonates demonstrating possible withdrawal from PCP [367, 368]. It is also excreted into breast milk,

where it may be present for up to 40 days after last maternal use and in concentrations of up to ten times plasma levels [369, 370].

Studies investigating the impact of intrauterine exposure to PCP have found it to cause symmetrical intrauterine growth retardation [371, 372]. In one study, 42.2% of infants had a birthweight for gestational age below the 25th percentile, and 45.7% had a head circumference below the 25th percentile; while clearly significant, these were less than a comparison group exposed to cocaine, in whom 55.1% and 67.9% of newborns were below the 25th percentile for birthweight and head circumference, respectively [372].

As ketamine is also known to cross the placenta, appropriate post-delivery care should be taken in those newborn infants who are born via Caesarean section under ketamine anesthesia [112]. A recent systematic review and meta-analysis of i.v. ketamine during spinal and general anesthesia for Caesarean section found no significant effects on neonates, though their findings were limited by a paucity of data for both maternal effects and neonatal well-being [373]. There are no human studies investigating the teratogenicity of ketamine or other arylcyclohexamines. Injections of 25 mg/kg ketamine of female dogs in their first trimester did not demonstrate any adverse effects to either the mother or her pups [374]. Another study found that ketamine potentiated

the teratogenic effects of cocaine in mice but that it was not teratogenic on its own [307, 375].

There are no data for MXE to be able to determine whether it crosses the placenta and/or whether it is excreted into breast milk.

There has been a significant change in the recreational drugs used throughout the world in the last 5–10 years, with increasing availability and use of a wide range of different new psychoactive substances (NPS, sometimes known as “legal highs”) [1, 2]. A popular emerging class of NPS is the synthetic cathinones. In 2013, there were approximately 35,000 drug seizures of NPS reported to the European Union Early Warning System (EU EWS), of which the most common substance category was cathinones (31%). In 2014, the EU EWS was notified of 101 previously unreported NPS (an increase of 25% from 2013), the largest category of these was cathinones ($n = 31$, 30.7%) [3]. Globally, cathinones was the third largest group of NPS to be reported by substance group (15%) in the same year [4]. Initially the cathinones, particularly mephedrone (4-methylmethcathinone), were sold undisguised by their chemical names, but they are also, like many other NPS, sold over the Internet and in “head shops” as “research chemicals,” “bath salts,” or “plant food,” often with warnings “not for human consumption” or “not tested for hazards” [3]. This marketing is an attempt to circumvent existing local, national, or international medicinal and/or drug laws [1].

Cathinone is the β -keto (β k) analogue of amphetamine (1-phenylpropan-2-amine) and is a naturally occurring alkaloid found in the fresh leaves of *Catha edulis* (also known as Khat) [5]. Khat typically grows in East Africa and the Arabian Peninsula and is chewed for its stimulant and psychoactive properties [6]. It has been linked to an increased risk of myocardial infarction, dilated cardiomyopathy, peptic ulcer disease, both acute and chronic liver disease, and oral cancers [7–11]. Synthetic cathinones represent a heterogeneous group of β -keto derivatives of ring-substituted phenylethylamines (amphetamine-related structures as the parent drug). The structure of phenylethylamine is shown in Fig. 1, the cathinones are β -keto derivatives, and most cathinones are a result of various R'-group substitutions to the phenylethylamine backbone as shown in Fig. 2.

Methcathinone was first synthesized in 1928 [12] and was the first synthetic cathinone

Fig. 1 Basic chemical structure of phenylethylamine

Fig. 2 Basic chemical structure of synthetic cathinones

produced [13]. Methcathinone, also known as ephedrone, was initially used as an antidepressant in the former Russian states in the 1930s and 1940s, but clinical utility of this and other cathinones has been limited, given the issues with abuse and dependence liability [14, 15]. This was first noted as a “street” recreational drug in Leningrad in 1982 and has been implicated in up to 20% of illegal drug trade in Russia in the 1990s [16]. Following this, harms associated with use have been described in other countries – Turkey [17], Israel [18], Eastern Europe [19, 20], and United States [16] – including cases with psychosis, stimulant toxicity, and in some incidences irreversible neurotoxicity (given manganese-containing ingredients associated with its manufacture). To our knowledge, bupropion (marketed under the trade name Zyban[®]) is the only cathinone that is currently licensed in any country and used as a medicinal product; it is licensed in the UK for use as an antidepressant and in smoking cessation [21].

There was then a hiatus in the recreational use of the synthetic cathinones until their appearance as NPS in recreational drug markets in the mid-2000s, and over 50 have been identified thus far [3]. While many synthetic cathinones have been reported as NPS [22], this chapter will focus on 4-methylmethcathinone (mephedrone) and 3,4-methylenedioxypyrovalerone (MDPV) as there is greatest evidence of their recreational use and a more extensive published literature on their pharmacological mechanisms of action and patterns of acute toxicity.

Prevalence and Pattern of Use

Mephedrone

To date, England and Wales are the only countries that collect national data at a population level on the use of mephedrone, through the Crime Survey England and Wales (formerly known as the British Crime Survey) [23]. The use of mephedrone in 2010/11 was reported by 1.1% of adults aged 16–59 and 4.4% of young adults aged between 16 and 24 years (approximately the same prevalence of use as cocaine) [24]; this covered the period during which mephedrone was classified as a Class B, Schedule I drug and a generic definition for the control of cathinone derivatives was accepted by the Home Office (April 2010). There was a subsequent decrease in the proportion of 16- to 59-year-olds reporting last year use of mephedrone to 0.5% in 2012/2013 and 0.6% in 2013/2014 [25]. There was also a decrease in the proportion of 16- to 24-year-olds reporting last year use of mephedrone to 1.6% in 2012/2013 and 1.9% in 2013/2014 [25]. Mephedrone use is positively associated with frequency of nightclub visits, 20 times higher (the largest difference across all types of drugs measured in the Crime Survey of England and Wales) with greater than four visits or more in the past month (4.4%) compared to no visits (0.2%) in the 2012/2013 dataset [26].

Further subpopulation surveys have revealed higher use of mephedrone among students, those who frequent night-time economy venues, and the men who have sex with men (MSM) community [27–29]. In a questionnaire survey of mephedrone use of 1,006 school ($n = 349$) and college/university ($n = 657$) students undertaken in Scotland in February 2010 (prior to the UK classification of mephedrone in April 2010), 205 (20.3%) of those surveyed had used mephedrone on at least one occasion. Additionally, 4.4% reported using mephedrone on a daily basis and were 21 years or younger [27]. A focus group of 154 pupils (aged 14–15) in Northern Ireland were surveyed in 2010. Approximately 40% admitted trying mephedrone at least once and approximately 70% stated that their friends had tried or used mephedrone [29]. Of 308 respondents to surveys

conducted in two “gay-friendly” nightclubs in South London in 2010, 54% reported lifetime use of mephedrone and 52% reported use within the last year [28].

Another subpopulation group in which there have been reports of a higher prevalence of mephedrone use is intravenous drug users – this has particularly been noted in Eastern Europe and the UK Channel Islands. A qualitative analysis in Hungary among 17 voluntary participants (eight male, nine female, age range 18–62 years) in a needle exchange program reported a switch to injecting mephedrone over “old drugs” (heroin and amphetamines) [30].

Although population level surveys are only available from England and Wales, on the basis of subpopulation surveys, it appears that there are significant international differences in the prevalence of mephedrone use. The 2014 Global Drug Survey demonstrated last year use of mephedrone in the UK of 7.9% in the 7,326 participants (19th position out of 20 reported drugs) and of 1.2% in Hungary in 3,239 participants (22nd position out of 26 reported drugs). Mephedrone was not listed in surveyed participant responses from the USA, Australia, New Zealand, and other European and South American countries [31]. Other sources of drug use data, however, may demonstrate NPS use, particularly mephedrone, in these countries. For example, the National Drug Strategy Household Survey in Australia questioned respondents about past 12-month NPS use for the first time in 2013 (mephedrone was listed as an example in this category) – 0.4% (approximately 80,000 people) confirmed use [32]. The last European School Survey Project on Alcohol and Other Drugs (ESPAD) study, which surveys youth around Europe regarding illicit drug use, was conducted in 2011 and did not include cathinone use or synonyms [33]. Finally, the Monitoring the Future Studies, which survey college students and adults (aged 19–55) in the United States, added “bath salts” in 2012. The term “bath salts” is usually colloquially used in the USA to refer to NPS such as cathinones, and in particular MDPV. The annual reported prevalence of use rate for “bath salts” was low at 0.8%, 0.6%, and 1.3% in Grade 8 (7,300), 10 (6,450), and 12 (6,300) students,

respectively. In 2014, the prevalence rates remained comparable at 1.0%, 0.9%, and 0.9% for Grade 8, 10, and 12 students, respectively. The annual prevalence of use for college students was 0.3% in 2012 and 0.2% in 2014 and for young adults (defined as aged 19–28) was 0.5% in 2012 and 0.4% in 2014 [24, 34].

Analytical Detection of Mephedrone in Wastewater Analysis and Other Subpopulation Studies

Wastewater analysis provides a nonintrusive way of measuring drug use within general or subpopulation groups. Analysis of anonymous pooled urine samples from street urinals in nine cities in the UK on one night in April 2014 showed that the most common NPS was 4-methylmethcathinone (five cities); the only other cathinone detected was methylone (London only) [35]. This same research group were involved in collection of pooled urine samples from one urinal outside a nightclub in central London, over 1 weekend for analysis; mephedrone was detected at a median concentration of 2965.1 ng/ml (2444.4–3323.8), as well as metabolites, but no other cathinones [36]. Wastewater analysis in one city in Australia demonstrated a peak in mephedrone use from 2009 to 2010, an 11-fold increase in use was demonstrated within this time frame; however, a reduction of measured concentration by half was observed comparing data from 2010 to 2011 (raw values not expressed) [37]. Wastewater analysis was conducted over two consecutive years (2010 and 2011) at an annual music festival in Australia. Daily composite wastewater samples, representative of the festival, were collected from the on-site wastewater treatment plant (WWTP) in 2010 and compared with data collected at the same time from a nearby urban community. Mephedrone and methylone were the only cathinones detected during this time. Daily mass loads (per 1000 people) of mephedrone halved between the two festival years; in 2010, mephedrone increased from <0.001 mg/day/1000 people on day 1 to 1.9 mg/day/1000 people on day 6. In 2011, mephedrone was detected at a concentration of <0.001 mg/day/1000 people on day 1 compared to 0.9 mg/day/1000 people on day 6 [38]. Composite raw

wastewater samples were collected from WWTPs in 17 cities in Italy (sampled once a year from 2010 to 2013). Mephedrone was detected only in Bologna (12/14 samples were above the limit of quantification; range 1–23.6 ng/L, years detected were unspecified) and Florence (1/14 samples tested positive; 1.6 ng/L, November 2013) which is consistent with a low population prevalence [39]. Khat and mephedrone were the only cathinones screened for in similar wastewater analysis collected from Oslo, Hamar, and Bergen (Norway) in July 2012 and were not detected although limitations around mephedrone stability were highlighted especially with long in-retention sewage times as well as storage techniques [40]. This may be a cause for underestimation of cathinone/mephedrone use in wastewater analysis and has been highlighted elsewhere [41, 42].

Drug samples submitted by users over a 2-year period (2010–2012) to Energy Control, a nongovernmental organization working among recreational drug users in Spain, were analyzed for the presence of cathinone derivatives [43]. Of the 6199 samples analyzed, cathinone derivatives were detected in 228 cases; MDPV was detected in 6.8%, methylone and mephedrone were the most frequently detected (24.9% and 24.5% respectively).

MDPV

Unlike mephedrone, there have been no coordinated national or European population surveys on MDPV use. Data on prevalence of use is, therefore, based on subpopulation surveys many of which focus not just on MDPV but also – particularly in North America – on “bath salt” prevalence as a surrogate for MDPV use. This is possible because there has been greater focus on MDPV use in North America. One study involved an analysis of samples purchased online in California and the general Internet (from USA sites only), between August 11 and December 15, 2011. The majority (32/35, 91%) had one ($n = 15$) or multiple cathinones ($n = 17$) present. Of the fourteen cathinones identified, MDPV was the most common ($n = 19$, 54.3%)

[44]. Additionally, Spiller et al. [45] reported on a retrospective case series of patients with exposures to bath salts from two US poisons centers over January 2010 to February 2011; 19 out of 236 recorded patients had blood and/or urine analyzed using GC/MS; MDPV was detected in blood samples of 13 out of 17 live patients (range 24–241 ng/mL, mean 58 ng/mL) as well as three out of five urine samples (range 34–1386 ng/mL, mean 856 ng/mL). No other synthetic cathinones were detected. The annual “MixMag” Drug Surveys, a UK-based project, reported on MDPV use in UK respondents (the country-specific breakdown of respondents was not provided) in the 2010/11 survey; 4.4% respondents reported that they had ever used MDPV and 3% reported that they had used MDPV in the last year (the total number of respondents was not reported) [46]. Notably, 3,4-methylenedioxypyrovalerone use was not reported in the “MixMag” Global Drugs Surveys from 2012 onwards (which were advertised to respondents worldwide), although 12% of UK respondents (22,000 participants worldwide, the fraction of UK respondents was not specified) in 2013 said they had used drugs promoted as “bath salts,” “legal highs,” or “research chemicals” in the previous 12 months (while these terms often are used to refer to cathinones, and as noted above in particular to MDPV, it is possible that respondents may not specifically be referring to these substances but to other NPS) [47]. In a self-report survey over 3 months among multicenter university students in Southeastern USA, 25 (1.07%) of 2349 respondents reported ever using “bath salts or MDPV” [48].

Analytical Detection of MDPV in Wastewater Analysis and Other Subpopulation Studies

Other analyses providing clues regarding community prevalence of MDPV use have included analysis of wastewater. Urinary metabolite assessment in one city in Australia demonstrated a sevenfold rise in MDPV use from 2009 to 2011 (raw values not expressed) [37]. MDPV has not been detected thus far in consequential wastewater analysis in the UK or the USA [35, 36]. Finnish wastewater

analysis (involving nine WWTPs) spanning the metropolitan area, university cities, and rural towns was conducted over 8 days in August 2012. MDPV was detected in only one town (Savonlinna, in the east), where the concentration was higher than that of the limit of detection during all 8 days of the study (maximum concentration: 5.1 ng/L, mass load of 1.9 mg/1000 people/day). No other cathinones were detected [49]. Other wastewater analysis have, however, confirmed its use in other Finnish cities, outside Savonlinna, within the same year (May 2012) such as Helsinki (2.4 mg/1000 people/day) and the Lappeenranta region (19 mg/1000 people/day) [50].

In Finland and Sweden, MDPV metabolites were discovered in urine samples of opioid-dependent patients undergoing opioid substitution therapy (9 of 34 samples) [51] and 21 (24.1%) of 87 addiction center patients [52] respectively, suggesting the potential that MDPV, like mephedrone, may be commonly used among those who use classical drugs and/or intravenous drug users. Also, a similar possible preference for injecting MDPV use (essentially thought to be amphetamine switching in opioid-dependent patients) was noted in clientele surveys of a large needle exchange program in Hungary [53]. In Finland, 3,4-methylenedioxypyrovalerone has been detected as a culprit agent among those arrested for driving under the influence of drugs (DUID) in 5.7% of 4570 of cases, where alcohol was also not detected [54].

Route of Administration and Dosage

Table 1 summarizes the main forms, routes of use, doses, and duration of effects for mephedrone and MDPV. The main routes of mephedrone and MDPV administration in recreational users are reported to be oral ingestion and nasal insufflation; oral ingestion may be of powder directly, dissolved in drinks or wrapped in cigarette papers (also known as “bombing”). Like mephedrone, there have been reports of intravenous use of MDPV as well as substitution recreational drug use by individuals with known injecting use of

Table 1 Forms of drug and common dosing and observations of use

	Mephedrone	MDPV
Chemical name	4-methylmethcathinone	3,4-methylenedioxypyrovalerone
Systematic chemical name	(<i>RS</i>)-2-methylamino-1-(4-methylphenyl)propan-1-one	(<i>RS</i>)-1-(benzo[d][1,3]dioxol-5-yl)-2-(pyrrolidin-1-yl) pentan-1-one
Forms	Powder (most common), powder-filled capsules, tablets.	Powder (most common), powder-filled capsules, tablets, blotters (small paper doses for sublingual/buccal administration), liquids and vegetable material
Physical characteristics	White crystalline in nature but may be light yellow or light brown	Brown or yellow-green amorphous powder
Mode of consumption	Nasal insufflation (most common) Oral ingestion (most common) Per rectum Intravenous Intramuscular Bombing ^a	Nasal insufflation (most common) Oral ingestion (most common) Per rectum Intravenous Sublingual Smoked Intramuscular Bombing ^a Dabbing ^b
Initial dose range per session (mg)	75 – 250 (oral) ^c	5-11 (insufflated) ^c 8 - 15 (oral) 6-12 (rectal)
Peak onset (mins)	15 - 45 ^a	30-60 (oral) 15-30 (insufflated)
Duration of action (hours)	2-3	2-7 (oral) 2 – 3.5 (insufflated)

^awrapped in cigarette wrapper and ingested

heroin/opioids [53, 55]. Given the observed short peak onset to action times, users have reported taking repeated doses per session up to 1 g for mephedrone [56] and 200 mg per session of MDPV [57]. This trend to re-dose in a session has been observed with most routes of drug consumption, as highlighted in Table 1.

Legal Status

Mephedrone and MDPV are not recognized medicinal products and are not used for the synthesis of any other products or active pharmaceutical ingredients. Since 2010, generic legislation in the UK classifies a range of different synthetic cathinones as Class B, Schedule 1 drugs (this generic classification covers both MDPV and

mephedrone and implies legally enforceable penalties including imprisonment associated with supply) [58]. In Europe, following review of both mephedrone in 2010 and MDPV in 2014 under the procedure for risk assessment and control of NPS set up by the European Council Decision 2005/387/JHA, both substances were risk assessed by the European Monitoring Centre for Drugs and Drugs Addiction (EMCDDA) Scientific Committee; the outcome of this risk assessment lead to the Council of the European Union to recommend their control by all European member states [59, 60]. There are legal controls surrounding manufacture, distribution, sales, and use of both mephedrone and MDPV in the USA [61], Canada [62], New Zealand [63], and Australia [64]. Most recently, on the counsel of the World Expert Drug Committee Review, mephedrone and

Fig. 3 Chemical structure of mephedrone

Fig. 4 Chemical structure of MDPV

MDPV have been added to schedule 2 of the United Nations Convention on Psychotropic Substances of 1971 [65, 66].

Biochemistry and Clinical Pharmacology

Mephedrone

Mephedrone was first synthesized in 1929 as a homologue of ephedrine [67]. The systematic chemical (International Union of Pure and Applied Chemistry, IUPAC) name is (*RS*)-2-methylamino-1-(4-methylphenyl)propan-1-one. Mephedrone is a synthetic ring-substituted cathinone closely related to the phenethylamine family, differing only by a keto functional group at the beta carbon as shown in Fig. 3. The molecular formula for mephedrone is $C_{11}H_{15}NO$, and it has a molecular weight of 177.242 g/mol.

The main synthetic route for mephedrone involves α -bromination of 4-methylpropio-phenone. The resulting compound (4-methyl-2-bromopropiophenone) is then reacted with methylamine hydrochloride and triethylamine in an acidic scavenger to produce 4-methyl-methcathinone. The hydrochloric salt form is both stable and water soluble [60].

3,4-Methylenedioxypropylphenylpropan-1-one

The systematic chemical IUPAC name for MDPV is 1-(1,3-benzodioxol-5-yl)-2-(pyrrolidin-1-yl)pentan-1-one. Its molecular formula is $C_{16}H_{21}NO_3$, equating to a molecular weight of 275.343 g/mol. 3,4-Methylenedioxypropylphenylpropan-1-one is the methylenedioxy derivative of pyrovalerone (Fig. 4). Pyrovalerone is controlled as a Schedule IV drug under the 1971 United Nations Convention (the scheduling relates to the potential a

substance has to be abused and the harms associated with its abuse and therefore the restrictions required on the substance from Schedule I (most restrictive) to Schedule IV (least restrictive)) [68]. The synthesis of MDPV is described in patents from France, Germany, the United Kingdom, and the USA all from the 1960s [69, 70]. Briefly, the precursor 1-(1,3-benzodioxol-5-yl)pentan-1-one is α -brominated to form a 2-bromopentan-1-one intermediate. Reaction of the intermediate with a pyrrolidine ring yields MDPV [71].

Pharmacokinetics

There is one pharmacokinetic study regarding mephedrone use in healthy volunteers [72] but no detailed human pharmacokinetic studies regarding MDPV. Most studies thus far involve in vitro human cells, in vivo animal models, and metabolites analyzed from single human cases. Extrapolation of information from drug user forums as well as plasma concentrations in users, particularly in the case of mephedrone, has informed experimental doses in rat models sufficient to achieve some translational value in humans.

Mephedrone

There are several studies assessing the pharmacokinetic parameters of mephedrone in rats. In Sprague–Dawley rats, the bioavailability of mephedrone (30 and 60 mg/kg) was 10% and protein binding was 21%. Peak concentrations were achieved between 0.5 and 1 h and decreased to undetectable concentrations by 9 h. The plasma concentrations after intravenous administration (10 mg/kg) fitted a two-compartment model

($\alpha = 10.23 \text{ h}^{-1}$, $\beta = 1.86 \text{ h}^{-1}$) [73]. The uptake and elimination of a single dose (5.6 mg/kg subcutaneous [s.c.]) of mephedrone was also determined to be rapid in a further rat model. The peak plasma concentration (C_{max}) observed was 1206 ng/ml with a T_{max} of 0.25 h [74]. Additionally, mephedrone readily enters the brain; a concentration of 4 ng/mg was observed after injection (1 mg/kg) at 2 min and almost totally cleared within an hour (0.4 ng/mg) [75, 76].

The metabolite pattern of mephedrone varies with route of administration. Meyer et al. [77] examined the metabolite pattern after oral administration in Wistar rats. In addition to the parent compound, the metabolites detected in urine were nor-mephedrone, nor-dihydro mephedrone, hydroxytolyl mephedrone, and nor-hydroxytolyl mephedrone. Urine was collected over a 24-h period, and therefore it was not possible to elucidate timing of metabolite formation. Urine samples were analyzed from one human subject (patient) in the same study and a further metabolite was identified, 4-carboxy-dihydro mephedrone (the patient self-reported oral ingestion of both butylone and mephedrone powder); there was no information regarding timing of urine collection in this case. These metabolites have been detected elsewhere in a similar rodent study [73]. Pedersen et al. [78] used cDNA-expressed CYP enzymes and human liver microsomal preparations and found cytochrome CYP2D6 to be the main enzyme responsible for the in vitro metabolism of mephedrone. Experiments involving a range of recombinant CYP isoenzymes resulted in the formation of the metabolites hydroxytolyl- and nor-mephedrone from CYP isoenzymes 1A2, 2B6, 2C8, 2C18, 2C19, and 3A4. However, it appeared that CYP2D6 had a more significant role in the metabolism of mephedrone compared to other enzymes. In particular, inhibition of CYP2D6 with quinidine significantly reduced mephedrone metabolism, with only about 20% of the parent compound having metabolized after 140 min, compared to approximately 60% with no inhibition. This 20% metabolism might have been due

to the action of other NADPH-dependent enzymes, as no metabolism was observed with the control that lacked NADPH. In the human liver microsomes and S9 fraction experiments, only formation of hydroxytolyl mephedrone metabolite was observed, as well as the same pattern of mephedrone metabolism with predominant CYP isoenzyme 2D6. Analyses of blood and a urine sample in four forensic traffic accidents with blood mephedrone concentrations ranging from 1 to 51 $\mu\text{g/kg}$ have yielded two further previously undocumented mephedrone metabolites – dihydro-mephedrone and 4-carboxy-mephedrone [78].

Kavanagh et al. [79] examined the pyrolysis products produced by heating mephedrone under simulated “meth pipe” conditions. Thirteen pyrolysis products were identified; the major ones being *iso*-mephedrone, 4-methylpropionophenone, 4-methylphenylacetone, two pyrazine derivatives (formed by dimerization of mephedrone), *N*-methylated mephedrone (*N,N*,4-trimethylcathinone), two hydroxylated oxidation products, and a di-ketone (there is no information regarding which of these or other metabolites have activity). This highlights the need to study all modes and routes of drug consumption to fully appreciate the pharmacological and/or toxicokinetic profile and impact of the mode of administration on these parameters. There are some discussion narratives on Erowid and other online drug forums documenting the experiences of several individuals with both MDPV and/or mephedrone pyrolysis, but interest appears relatively limited, with only 5–10 users commenting in discussion threads; most of these were deterred as a result of concerns over drug efficacy or safety. Effects were described as “fast” and short-lived, at times as being “harsh” on the throat and lungs [56].

Recently, urine samples were obtained pre-dose and after 4 h from two healthy Caucasian recreational drug users (aged 29 and 36 years) who were given a single oral dose of 200 mg of mephedrone in a controlled administration study [72]. Both were extensive-intermediate CYP2D6 metabolizers. A rapid urine test for main drugs of

abuse was negative before administration. Urine samples were collected before and 4 h after the mephedrone ingestion. The following metabolites characterized for structural elucidation were classified as M1–M10. These included six phase I (M1–M3, M5–M7) and four phase II (M4, M8–M10) mephedrone metabolites. The metabolites previously described in humans or other species were N-demethylmephedrone (M1, C₁₀H₁₃NO), 1-dihyromephedrone (M3, C₁₁H₁₇NO), 1-dihydro-nor-mephedrone (M5, C₁₀H₁₅NO), 49-hydroxymethyl-mephedrone (M6, C₁₁H₁₅NO₂), 49-carboxymephedrone (M7, C₁₁H₁₃NO₃), and 49-carboxymephedrone (M9, C₁₇H₂₁NO₉) [46, 50, 51]. N-demethylmephedrone-3-carboxylic acid (M2, C₁₀H₁₁NO₃), N-succinyl nor-mephedrone (M4, C₁₄H₁₇NO₄), hydroxylmephedrone-3-*O*-glucuronide (M8, C₁₇H₂₃NO₈), and a hydroxylated metabolite of nor-mephedrone (M10, C₁₆H₂₀NO₈) were reported for the first time in this study.

Reported data from user forums suggests that the onset of desired effects of mephedrone varies with route of administration, although there have been no controlled administration studies to corroborate this. Insufflation and intravenous routes are reported to be associated with the onset of effects within a few minutes, compared with 10–45 min when ingested. The duration of action is reported to be between 2 and 4 h, however, can be as short as 30 min with intravenous use. Rectal administration has been reported to have a more rapid termination of effects relative to oral doses, lasting approximately 20 min but absorption is variable. Intranasal and intravenous uses are reported to be associated with a greater compulsion to re-dose to maintain effects [56, 80].

Human blood–brain permeability has been simulated using an in vitro model of conditionally immortalized human brain endothelial cells (TY09) [81]. Permeability coefficient (Pe) ratios indicate the blood–brain barrier permeability of the drug in relation to the extracellular marker lucifer yellow (Pe = 1) with high permeability being a Pe ratio >3 and a very high permeability being a Pe ratio >10. The Pe of mephedrone was

>10 (apical to basolateral transport 14.0 ± 10.4 , basolateral to apical 12.2 ± 6.1) indicating that it has a very high blood–brain barrier permeability [76].

3,4-Methylenedioxypropylvalerone

There have been three studies that have investigated pharmacokinetic parameters of MDPV; two have investigated MDPV metabolism [82, 83] and one has investigated blood–brain barrier permeability [76].

The first study investigating the metabolism of MDPV was an in vitro study. This involved incubation of 1 mL of 1 mg/mL MDPV with 6.5 mL of human liver microsomes and S9 cellular fractions (P450 and transferases) [82]. Eighty percent of the MDPV remained unchanged, which the authors felt may have been related to the dose of MDPV used saturating their model; only a single dose was studied. Approximately 7% of the MDPV was metabolized to catechol pyrovalerone and 10% to methylcatechol pyrovalerone. Neither of these metabolites was found in the second study [83].

Metabolism of MDPV was also investigated using an in vitro human liver microsomal model and in vivo experiments in rats administered MDPV as a single dose of 20 mg/kg via gastric intubation. Urine was collected from the rats over a 24-h period, and additional urine samples from human MDPV users were also analyzed to allow confirmation of metabolites [83]. The metabolites from this study are listed in Table 2. Human enzyme incubations were performed of the ten most important CYP enzymes, assessed by capability to catalyze the formation of the initial metabolite of MDPV, demethylenyl-MDPV, in vitro. The amount of metabolism was: CYP 2C19 (100%), CYP 2D6 (<50%), CYP 1A2 (<50%), and CYP 2A6 (<10%). Phase I metabolites included MDPV-M (demethylenyl-), MDPV-M (demethylenyl-methyl-) MDPV-M (demethylenyl-methyl-oxo-), MDPV-M (oxo-), MDPV-M (demethylenyl-methyl-hydroxy-alkyl-),

Table 2 Pharmacokinetic profile of mephedrone and MDPV

	Mephedrone	MDPV

^bListed as found in Meyer et al. (2010) [77]. The seventh and eighth listed metabolites were derived from DNA-expressed CYP enzymes and human liver microsomal preparations used as well as analysis of urine of persons from forensic traffic cases (Pedersen, Reitzel, Johansen, & Linnet, 2013) [78]. The last four were derived from human case studies (Pozo et al., 2015) [72].

^cThe first three metabolites listed as per Strano-Rossi (2010) [82]. The remaining metabolites listed from human case studies (Meyer, Du, Schuster, & Maurer, 2010) [83].

MDPV-M (demethylenyl-hydroxy-alkyl-), MDPV-M (demethylenyl-hydroxy-phenyl-), and MDPV-M (demethylenyl-oxo-). Besides the unchanged parent compound, the following metabolites were also found in human urine after the intake of an unknown amount of MDPV: demethylenyl-MDPV, demethylenyl-oxo-MDPV, oxo-MDPV, demethylenylhydroxy-alkyl-MDPV, and demethylmethyl-N,N-bisdealkyl-MDPV. These three metabolites were also present in rat urine: demethylenyl-methyl-MDPV, demethylenyl-methyl-oxo-MDPV, and demethylenyl-methylhydroxy-alkyl-MDPV. Phase II metabolites were predominantly excreted as glucuronides and sulfates.

3,4-Methylenedioxypropyvalerone has a high Pe ratio, indicating its likely ability to cross the blood–brain barrier. Subanalyses showed that apical to basolateral transport of MDPV was greater than basolateral to apical transport (Pe ratios for apical to basolateral transport 37.2 ± 11.3 , and basolateral to apical as 12.0 ± 11.2 , $p < 0.05$); this suggests an active transport mechanism of MDPV, possibly through influx carriers. However, the particular transporters implicated in this prototype blood–brain barrier model were not studied [76].

Data from drug user forums suggests that the onset of effects of MDPV when taken orally is 15–30 min (duration 2–7 h) and after nasal insufflation the onset is within 5–20 min of use (duration 2–3.5 h). Most report a come-down effect around 30–60 min orally and close to 15–30 min after insufflation. Onset intravenously is within minutes, and users report a compulsion to re-dose [84].

Pharmacodynamics and Mechanisms of Toxic Effects

A number of recent studies have assessed the binding affinity to monoamine receptors and proposed structure-activity relationships of mephedrone and MDPV. These have increased our understanding of the potential cardiovascular, neurological, and thermoregulatory effects of using these drugs in humans. Convergent lines

of evidence from a heterogenous mix of in vitro and in vivo cell studies as well as animal models suggest that there is modulation around serotonergic, dopaminergic, and noradrenergic transmission and interaction with monoamine transporters to achieve this (as summarized in Table 3).

Simmmler et al. [76] were the first to attempt categorization of cathinones as fitting into three groups based on the variation in their selectivity for transporters of dopamine (DAT), noradrenaline (NET), and serotonin (SERT) and potency to act as monoamine transport inhibitors/substrate releasers shown in Table 4.

Mephedrone

Animal Data

Neurochemistry

Mephedrone stimulates dopamine release and blocks its reuptake through its interaction with the DAT and has displayed affinity to various serotonin receptor subtypes. Early research with in vitro experiments in isolated synaptosomes from rat cortex or striatum demonstrated mephedrone inhibition of serotonin (5-HT) –uptake with an IC_{50} value lower than that of dopamine (DA) uptake ($IC_{50} = 0.31 \pm 0.08$ and $0.97 \pm 0.05 \mu M$, respectively) [50]. Additionally, mephedrone displaced competitively both [3H]paroxetine (used to label SERT) and [3H]WIN35428 (used to label DAT) binding in a concentration-dependent manner (K_i values of $17.55 \pm 0.78 \mu M$ and $1.53 \pm 0.47 \mu M$, respectively), indicating a greater affinity for DAT than for SERT. Through radioligand binding of [3H]ketanserin (used to label 5-HT $_{2A}$ receptors) and [3H]raclopride (used to label dopamine D $_2$ receptors) in rat membranes, it was determined mephedrone had a greater affinity for the 5-HT $_2$ than for the D $_2$ receptors. Interestingly, the affinity of mephedrone for SERT was lower than the IC_{50} value of mephedrone inhibiting 5-HT uptake, indicating that an additional mechanism to the reversible interaction with the 5-HT transporter is possible. There may be competitive inhibition

Table 3 Pharmacodynamic effects of mephedrone and MDPV on catecholamine transporters DAT, NET, SERT

Mephedrone		MDPV
Monoamine uptake inhibiton (IC ₅₀ , nM ± s.e.m.)		
DAT	762 ± 79	4.1 ± 0.5
NET	487 ± 66	26 ± 8
SERT	422 ± 26	3349 ± 305
Monoamine release (EC ₅₀ , nM ± s.e.m.)		
DAT	51 ± 5	2.3 ± 0.8
NET	58 ± 11	13 ± 16
SERT	122 ± 10	Inactive

EC₅₀ and IC₅₀ numbers taken from (Baumann et al., 2013) [70].

Table 4 Basic groups of cathinones as per their monoamine profile and resemblance to profiles of classical stimulant recreational drugs

Group	Example Cathinones
Cocaine-MDMA-Mixed Cathinones (substrates for DAT, SERT and NET)	mephedrone, methylone, ethylone, butylone and naphyrone.
Methamphetamine-like Cathinones (monoamine transporter substrates with DAT selective profiles)	cathinone, methcathinone, flephedrone
Pyrovalerone-cathinones (non-substrate transporter inhibitors)	MDPV, Pyrovalerone

with 5-HT itself [85]. Eshleman et al. [86] have studied the effects of 5-HT subreceptor profiles indicating that it behaves as an antagonist at receptor level and also confirms low potency at h5-HT2A: [¹²⁵I]DOI binding site and low potency to stimulate inositol monophosphate accumulation, a measure of receptor function with IC₅₀ 14.8 ± 1.8 μM. Mephedrone also has low potency to interact with h5-HT2C to achieve

inhibition of 5-HT- stimulated IP-1 formation (IC₅₀ > 440 μM). This confirms that mephedrone is unlikely to share a direct interaction as an h5-HT2A receptor agonist.

Further, Eshleman et al. [86] demonstrated similar receptor profile interactions as above, mephedrone displayed high potency to induce release of preloaded neurotransmitter from monoamine transporters (NET > DAT and SERT) and

thus acts as a transporter substrate. High K_i values for inhibition of binding at hDAT $4.80 \pm 0.75 \mu\text{M}$, hSERT $21.0 \pm 4.8 \mu\text{M}$, and hNET $11.8 \pm 4.0 \mu\text{M}$ compared with IC_{50} values of inhibition of neurotransmitter uptake for hDAT [^3H]DA $0.098 \pm 0.027 \mu\text{M}$, hSERT [^3H]5-HT $0.51 \pm 0.15 \mu\text{M}$, and hNET [^3H]NE $0.0536 \pm 0.0087 \mu\text{M}$, respectively, indicate a higher inhibitory potency at uptake compared to binding and generally induced release of preloaded [^3H]neurotransmitter from hDAT, hSERT, and hNET (highest potency at hNET: EC_{50} hDAT[^3H]DA $1.19 \pm 0.34 \mu\text{M}$, hSERT[^3H]5-HT $11.9 \pm 4.9 \mu\text{M}$, and hNET[^3H]NE $0.41 \pm 0.13 \mu\text{M}$), and thus behaves as a transporter substrate.

Neurocytotoxicity

Studies to date do not demonstrate definitive cytotoxic effects of mephedrone at nerve endings. Female C57BL/6 mice (20–25 g) were given mephedrone under binge-dosing regimens (four injections of 20 or 40 mg/kg with 2-h intervals) attempting to reproduce conditions of similar reported human consumption patterns; mephedrone was not toxic to dopaminergic nerve terminals of the striatum as well as surrogate features of serotonergic damage [87]. However, similar studies investigating the effects of mephedrone on 5-HT nerve terminals are equivocal [88, 89]. In one study, Hadlock et al. [88] demonstrated that repeated mephedrone administrations (4×10 or 25 mg/kg s.c. per injection, 2-h intervals) in male Sprague–Dawley rats (290–400 g, $n = 6$ –10) caused persistent decreases in hippocampal serotonin (5-hydroxytryptamine; 5HT) transporter function and 5HT levels. This was observed 7 days after treatment compared with the saline-treated group (4.0 ± 0.6 , 3.5 ± 0.5 , and $2.1 \pm 0.2^* \text{ pg}/\mu\text{g}$ protein for saline, $4 \times 10 \text{ mg/kg}$, and $4 \times 25 \text{ mg/kg}$, respectively, $p \leq 0.05^*$). In contrast, mephedrone treatment was no different to saline treatment groups when assessing striatal dopamine (DA) transporter function or DA concentrations 7 days post administration (data not shown). Of note, these mice were kept in warmer environmental conditions ($\geq 27^\circ\text{C}$, housed three to four animals per cage). On the

other hand, Baumann et al. [89] did not demonstrate a change in amine concentrations of serotonin, noradrenaline, or dopamine in the striatum and frontal cortex of Sprague–Dawley rats (300–350 g) that underwent repeated administration of mephedrone versus saline, as measured 2 weeks post administration. Rats in this experiment were individually housed and under conditions of controlled temperature ($22 \pm 2^\circ\text{C}$), as well as lower doses of mephedrone were used (3×3 or 10 mg/kg s.c. per injection versus saline, 2-h intervals).

Interestingly, mephedrone's ability to serve as a DAT inhibitor could provide protection against methamphetamine-induced neurotoxicity through competitive inhibition. However, dopaminergic nerve toxicity associated with known doses of methamphetamine (four injections of 2.5 or 5.0 mg/kg at 2 h intervals) was not prevented by preinjection doses of mephedrone (10, 20, or 40 mg/kg) and was significantly enhanced [90]. Mephedrone also enhanced the neurotoxic effects of amphetamine and 3,4-methylenedioxymethamphetamine on DA nerve terminals; hence it interacts with the DAT in a manner unlike that of other typical DAT inhibitors. The status of 5-HT nerve terminals in the hippocampus of female C57BL mice (20–25 g) was assessed through measures of 5-HT, SERT, and tryptophan hydroxylase 2 (TPH2) in an identical experiment [91]. Mephedrone ($4 \times 20 \text{ mg/kg}$ s.c. injections, 2-h interval) did not cause persistent reductions in the concentrations of 5-HT, SERT, or TPH2 either when given alone or in combination with methamphetamine ($4 \times 5 \text{ mg/kg}$). The main effect of drug treatment on 5HT concentrations was significant ($F[3,30] = 5.02$, $p = 0.006$) but neither mephedrone nor methamphetamine alone changed hippocampal 5-HT concentrations. Mice were housed five per cage in a temperature-controlled room (temperature values not specified). Green et al. [92] have hypothesized the paucity of catechol metabolites which produce highly reactive intermediates capable of inciting free reactive oxygen species, such as in MDMA, which may explain the paucity of direct neurotoxicity observed with mephedrone.

Cardiovascular

There are both *in vitro* and *in vivo* studies evaluating the cardiovascular effects of mephedrone and MDPV. Overall these studies show that mephedrone is associated with significant tachycardia, moderate hypertension, with rapid time to peak onset and resolution of hemodynamic parameters. This finding has been confirmed in two separate animal-based studies. Meng et al. [93] performed a three-part study assessing the electrocardiographic, echocardiographic, and hemodynamic effects of mephedrone. Mephedrone (1–30 μ M) had little direct effect on voltage-dependent ion channel activation; maximum mean inhibition on human ether-a-go-go-related gene (HERG) coding K⁺ channels (on stably transfected Chinese hamster ovary cells (CHO)) was $9 \pm 2\%$, human Kv LQT1/mink (on CHO cells) was $0 \pm 2\%$, L-type calcium channels of isolated pig myocytes was $10 \pm 7\%$, and human Nav 1.5 cardiac ion channels (stably transfected in human embryonic kidney-293 (HEK-293) cells) was $4 \pm 3\%$ with a 30 μ M dose.

The effects of *subcutaneous* mephedrone injection ($n = 6$ –7 per group, 3 mg/kg or 15 mg/kg) on heart rate (HR) and mean arterial pressure (MAP) were tested in conscious telemetry-implanted rats, compared to saline controls. For heart rate, the pre-dose value for the saline-treated animals measured 347 ± 9 beats per minute (bpm) and for the 3 and 15 mg/kg mephedrone-treated groups this value measured 309 ± 5 and 324 ± 3 bpm (time = 0 min), respectively. A statistically significant tachycardia was observed in the mephedrone-treated group, peaking at 30% higher at 25 min (3 mg/kg group) and 39% higher than the pre-dose value 45 min after injection (15 mg/kg group). The heart rate of the saline-treated rats began to fall after 10 min and returned to pre-dose levels within about 30–40 min. In contrast, heart rate for the mephedrone-treated group continued to rise peaking at 30% higher than the pre-dose level 25 min following injection of 3 mg/kg and 39% higher than the pre-dose value 45 min after injection of 15 mg/kg. Heart rate remained significantly elevated compared to time-matched saline-treated animals for 105 min

after the 3 mg/kg dose and for 3 h following the 15 mg/kg dose.

Pre-dose values of blood pressure in the saline-treated group were measured as mean arterial, systolic, and diastolic, 107 ± 7 , 128 ± 7 , and 91 ± 7 mmHg, respectively. These same values for the 3 mg/kg mephedrone-treated group measured 106 ± 2 , 126 ± 3 , and 92 ± 2 mmHg, respectively. In the 15 mg/kg treatment group, these values measured 101 ± 3 , 120 ± 5 , and 86 ± 3 mmHg, respectively. All blood pressure measurements for the saline-treated group returned to levels close to pre-dose values within about 30–40 min following injection. In comparison, MAP increased in all treatment groups with a 10–15% peak increase above pre-dose measurements for the 3 mg/kg treatment group and 20–25% peak increase for the 15 mg/kg treatment group, seen within 1–2 h of dosing. These returned to normal within 3–4 h.

Interestingly, reserpine pretreatment (10 mg/kg) to mephedrone-treated rats (subcutaneous injection 15 mg/kg) demonstrated little change to saline-treated control rats (292 ± 7 bpm in the saline-treated group and 299 ± 6 bpm in the mephedrone-treated group, pre-dose MAP 90 ± 1 and 91 ± 3 mmHg in the saline and mephedrone-treated groups, respectively). The echocardiographic findings of anesthetized mephedrone-treated rats (1 mg/kg intravenously) resulted in significant increases in sonographically observed cardiac output (pre-dose 81.3 ± 3.0 ml/min, peak effect 95.0 ± 5.6 ml/min, 10 min post dose 87.6 ± 4.3 ml/min), stroke volume (pre-dose 205 ± 7 μ l, peak effect 223 ± 11 μ l, 10 min post dose 214 ± 9 μ l), ejection fraction (pre-dose $74.3 \pm 2.5\%$, peak effect $86.1 \pm 2.5\%$, 10 min post dose $79.3 \pm 3.2\%$), and impairment of diastolic relaxation (pre-dose 7.25 ± 0.14 mm, peak effect 7.04 ± 0.16 mm, 10 mins post dose 7.19 ± 0.20 mm). These are akin to the echocardiographic findings of rats injected with methamphetamine (given 0.3 mg/kg subcutaneously) (data values not reported).

The principal hemodynamic effects of tachycardia and moderate hypertension were reproduced by Varner et al. [94] when direct

comparisons with methamphetamine were again made. Conscious telemetry-implanted rats (housed individually) received either intravenous mephedrone ($n = 5$ for 0.01–0.1 mg/kg and $n = 7$ for 1–9 mg/kg) or methamphetamine ($n = 7$ for 0.01–9 mg/kg) or 0.9% saline controls. Pretreatment with atenolol (1 mg/kg) blunted the tachycardic response in mephedrone-treated rats (384 ± 10 to 352 ± 8 bpm). Additionally, pretreatment with phentolamine (3 mg/kg) reduced the pressor (114 ± 10 mmHg to 70 ± 5 mmHg) but increased tachycardic (363 ± 3 to 435 ± 24 bpm) responses to mephedrone (3 mg/kg) – presumed to be related to baroreceptor activity. The effect of both beta-adrenergic and alpha-adrenergic activation suggests catecholamine noradrenaline modulation in spite of the blunted effect observed in reserpinized rat. Baumann et al. [89] have explained this physiologically; *in vitro* studies on rat brain synaptosomes support mephedrone as having affinity to noradrenaline transporters (NET) and acting as a NET transporter substrate (release assays conducted using [3H]MPP+ as the radiolabeled substrate for NET; $EC_{50} = 62.7$ nM) resulting in the release of cytoplasmic stores of noradrenaline.

Central Behavior

Mephedrone rapidly increases locomotor activity and stereotypy in a dose-dependent fashion in rat models [89, 90, 95–101]. López-Arnau et al. [102] demonstrated mephedrone (5, 10 and 25 mg/kg) significantly increased spontaneous locomotor activity (measured as occlusions of photobeams in a 10-min period of horizontal activity within a framed box) of mice compared with saline controls (5 mg/kg; $201\ 806 \pm 21\ 894$ – AUC over 360 min vs. $72\ 829 \pm 9524$ for saline controls) lasting approximately 150 min. This hyperlocomotion could be partly reduced with pretreatment with ketanserin (0.5 and 4 mg/kg), a 5-HT₂ receptor antagonist, and haloperidol (0.1 and 0.25 mg/kg), a nonselective dopamine receptor antagonist, measured by about 53% and 65%, respectively, to baseline. Equally, they demonstrated a reliance on endogenous 5-HT given pretreatment with p-chlorophenylalanine (an inhibitor of 5-HT synthesis) decreased

locomotor activity by 53% from baseline controls (raw data not shown). Pretreatment with a selective antagonist of 5-HT_{1B} receptors did not have an effect. This receptor activation has been implicated with methamphetamine use. Additionally, Baumann et al. [89] demonstrated forepaw treading in mice ($F(2, 15) = 22.9$, $p < 0.0001$), a behavior associated with serotonin syndrome, in singly-housed mice enduring a repeat high-dosing regimen of mephedrone (10.0 mg/kg sc, 3 doses). The only reported human cases of serotonin syndrome with mephedrone involved aggregate toxicity with fluoxetine [103].

Mephedrone affects performance in complex motor and memory tasks. It dose-dependently degrades nonhuman primate performance on the rotating turntable and bimanual motor skill tasks, two measures of complex motor skill and procedural learning [101]. Den Hollander et al. [96] treated mice with a binge-like, multiday regimen of mephedrone (30 mg/kg, twice daily for 4 days) and demonstrated impaired recall performance in mice tasked with the Morris water maze. Other examples, of long-term memory degradation in similar multiday exposures (30 mg/kg s.c. once daily for 10 days) results in a failure to discriminate novel from familiar objects 35 days post exposure in adolescent rats [104]. This counteracts the short-term memory and visuospatial learning gains observed in singly-treated rhesus macaques (0.32 mg/kg) [101].

Thermoregulation

The effect of mephedrone effects on body temperature in animal models appear to be dependent on the context. In particular, whether the animals are grouped together versus singly-housed, the drug regimen, and ambient temperatures. Mephedrone (4 or 10 mg/kg) caused a transient decrease (raw data not provided, data are expressed as change in temperature (°C, mean \pm SEM) from the baseline reading taken at the time of injection) in rectal temperature compared with single i.p. injection of saline vehicle (1 mL/kg). Temperatures were measured at 20 min intervals over a 2-h period. The change in temperature with mephedrone peaked at 60 min with approximately -1.5 °C deviation from baseline with mephedrone 10 mg/kg doses.

Individually housed rats then received an i.p. injection of vehicle (1 mL/kg), 0.2 mg/kg prazosin HCl (α_1 -adrenoceptor), 1 mg/kg BRL 44408 maleate (α_2A -adrenoceptor antagonist), 2 mg/kg SCH 23390 HCl (D1 receptor antagonist), or 0.63 mg/kg L-741626 (D2 receptor antagonist), followed 30 min later by vehicle (1 mL/kg) or 10 mg/kg mephedrone HCl ($n = 6-7$ per group). In individually housed vehicle-pretreated rats, 10 mg/kg mephedrone caused a transient significant decrease in rectal temperature. The duration of the mephedrone-induced hypothermia was prolonged in the presence of all drugs with statistical significance compared to mephedrone alone; prazosin (20–60 mins) and SCH 23390 (20–80 mins). In contrast, mephedrone-induced hypothermia was unaffected by pretreatment with either BRL 44408 or L-741626 [72]. On the other hand, repeated high-dose mephedrone treatment (4×50 mg/kg/injection, s.c., 2 h intervals) in a manufactured *warm* environment causes significant and prolonged hyperthermia of up to 40.0 ± 0.1 °C average core body temperature over the 8 h treatment period [88]. Subsequent studies with lower doses of mephedrone (up to 10 mg/kg) have demonstrated mild hyperthermia [47, 48, 76], with core body temperatures rarely exceeding 38.0 °C. Persistent serotonergic deficits have only been reported under these hyperthermic and “binge-dosing” conditions [89].

MDPV

Neurochemistry

There are no formal pharmacodynamic studies evaluating the effects of MDPV in humans.

Based on rodent models, Baumann et al. [95] demonstrated MDPV (NET uptake IC_{50} 26 ± 8 nM, NET release EC_{50} 13 ± 16 nM, DAT uptake IC_{50} 4.1 ± 0.5 nM, DAT release EC_{50} 2.3 ± 0.8 nM) is a catecholamine-selective transporter blocker that displays greater potency than the prototypical transporter blocker cocaine (NET uptake IC_{50} 292 ± 34 nM, NET release EC_{50} 2190 ± 883 nM, DAT uptake IC_{50} 211 ± 19 nM, DAT release EC_{50} 151 ± 35 nM) particular at NET and DAT receptors, promoting in both

mechanisms the maintenance of dopamine and norepinephrine at the synaptic junction. MDPV is a potent uptake blocker at DAT and NET (50 and 10 times more potent than cocaine respectively), with weaker effects at SERT (10 times less potent than cocaine; MDPV SERT uptake IC_{50} 3349 ± 305 nM; SERT release EC_{50} inactive; cocaine SERT uptake IC_{50} 313 ± 17 nM; SERT release EC_{50} inactive).

Neurocytotoxicity

Only one study has assessed the potential for MDPV-related cytotoxicity. Simmler et al. [76] set up a cell membrane integrity assay using HEK-293 cells, which measures the release of adenylate kinase from damaged cells. Cell membrane integrity was maintained at concentrations of 10 μ M and 100 μ M after 4 h of incubation at 37 °C, suggesting that MDPV is not associated with cytotoxicity; however, more work is required to confirm these findings.

Central Behavior

Significant locomotor activity has been reported related to the stimulant MDPV effects [95, 105]. MDPV was 10 times more potent than cocaine in inducing motor hyperactivity tested as stereotypy (repeated interruption of the same photocell beam within 2 s) and forward locomotion (distance traveled in cm), measured for 1 h postinjection after subcutaneous administration of saline, MDPV 0.1–3.0 mg/kg or cocaine 3–17 mg/kg, twice a week while in the activity monitor. Stereotypy was significantly increased by administration of MDPV ($F[4,25] = 26.31$, $P < 0.0001$) and cocaine ($F[3,20] = 7.68$, $P < 0.001$). The threshold dose of MDPV capable of stimulating significant stereotypy is 0.3 mg/kg ($P < 0.05$, Newman–Keuls), while the threshold dose for cocaine was 3 mg/kg ($P < 0.05$, Newman–Keuls) [95]. Interestingly, MDPV produced time- and dose-dependent stimulation of locomotor activity in doses from 0.3 to 30 mg/kg. Stimulant effects of 1 and 3 mg/kg MDPV occurred within 10 min following injection and lasted 190 min. Following the 30 mg/kg dose, stimulant effects occurred after 80 min and lasted 300 min with a biphasic effect; activity depressed

between 10 and 50 min following injection. The ED_{50} values were calculated by estimating the dose producing half of the peak ambulation from the ascending linear portion of the generated dose response curve, MDPV (ED_{50} 1.26 ± 0.08 mg/kg) exceeded cocaine (ED_{50} 7.24 ± 0.14 mg/kg). There was full drug substitution in cocaine-trained rats (ED_{50} MDPV 0.68 mg/kg; ED_{50} cocaine 3.09 mg/kg) and methamphetamine-trained rats (ED_{50} MDPV 0.67 mg/kg; ED_{50} methamphetamine 0.37 mg/kg) [98, 105].

A number of in vivo animal studies have investigated the abuse potential of MDPV using models involving self-administration, intracranial self-stimulation, discrimination, substitution, and taste aversion. In a self-administration study in twenty-four male Wistar rats, MDPV was compared to methamphetamine [47]. The rats went through four sequential phases: lever-press training, drug self-administration acquisition (once daily 1 h self-administration sessions for 10 days, with a drug infusion of 0.05 mg/kg over the 1 h session), fixed-ratio dose response testing, and progressive-ratio dose response testing. Rats readily self-administered MDPV or methamphetamine at a per-infusion dose of 0.05 mg/kg on a fixed-ratio schedule of reinforcement with lever presses consistently favoring the drug-paired lever. Over seven nonfood-restricted sessions, the infusion rate of MDPV ($M = 19$; $SD = 22$; $Max-Min = 115-0$) was consistently higher than that of methamphetamine ($M = 8$; $SD = 7$; $Max-Min = 23-0$), while lever discrimination was similar for both MDPV ($M = 86\%$; $SD = 22\%$; $Max-Min = 100-8\%$) and methamphetamine ($M = 83\%$; $SD = 14\%$; $Max-Min = 100-33\%$).

Furthermore, the abuse potential of MDPV was studied [106]. Sprague-Dawley rats ($n = 48$) were trained to intravenously self-administer drugs every day for 10 days and were divided into four groups which self-administered two hour infusions of MDPV 0.05 , 0.1 , or 0.2 mg/kg or methamphetamine 0.05 mg/kg as a positive control. Self-administration of MDPV was maintained at all three doses. Also, MDPV administration ($F[4,35] = 11.549$, $p < 0.001$) at all tested doses compared to vehicle ($p < 0.05$)

significantly lowered thresholds of intracranial self-stimulation (ICSS) and has been noted elsewhere [107]. These findings may foreshadow compulsive consumption in humans and significant rewarding effects.

Cardiovascular

Pitcher et al. [108] demonstrated dose-dependent increases in heart rate (150%) in *Daphnia magna* (freshwater flea) with equimolar concentrations of synthetic cathinones including MDPV (combined EC_{50} of $1.9 \mu\text{M}$); tachycardic effects were alleviated with both calcium-channel blockers diltiazem and verapamil. Cardiovascular parameters were studied in four rats using telemetry transmitters inserted into the aorta to measure heart rate and blood pressure; subcutaneous doses of MDPV ($0.1-3.0$ mg/kg) were compared to cocaine ($3-17$ mg/kg) and saline control. MDPV administration was associated with tachycardia ($F[4,25] = 32.61$, $p < 0.0001$) and hypertension ($F[4,25] = 3.05$, $p < 0.05$). The peak increase in heart rate associated with MDPV administration was significantly greater with cocaine administration (3.0 mg/kg MDPV vs. 10 mg/kg cocaine, $p < 0.01$) [99] (raw data values not shown).

Thermoregulation

As is the case with mephedrone, the development of hyperthermic effects was not observed under all experimental paradigms. Doses of MDPV ($1-30$ mg/kg) did not increase core temperature in mice compared with saline controls at 20°C ambient temperatures. In contrast, at 28°C , a 10 mg/kg dose of MDPV resulted in a mild temperature rise in mice ($\sim 2^\circ\text{C}$, 10 mg/kg) compared with a similar dose of MDMA ($\sim 6^\circ\text{C}$, 10 mg/kg) [98]. Another study has reproduced a similar result, MDPV effect on temperature was only modestly hyperthermic in male Wistar rats housed in humidity and temperature-controlled environment ($23 \pm 1^\circ\text{C}$); it was higher after MDPV injections of 1.0 mg/kg than after 5.6 mg/kg by the end of the session (180 min postinjection time bin) (raw data values not shown) demonstrating a trend towards hypothermic response at higher ranges. Area-under-the-curve (AUC) measures (summed deviations from the mean of the vehicle

condition) were determined for locomotor activity (represents counts per minute of changes in signal strength from the radiotelemetry transmitter) and body temperature for MDPV and d-methamphetamine. The AUC for body temperature was higher for d-methamphetamine than for MDPV following the 5.6 mg/kg dose but not for the 1.0 mg/kg dose even though the AUC data for activity was significantly higher for MDPV than d-methamphetamine for the 5.6 mg/kg dose but not for the 1.0 mg/kg dose [75]. It would appear that methamphetamine and MDMA elicit greater hyperthermia responses in rats than MDPV alone.

Clinical Presentation

Human Data on Acute Toxicity

Information regarding clinical toxicity of mephedrone is synthesized from reports to drug user forums, calls to regional/national poisons information services, single case reports, and case series. The main limitation of many of these reports or studies is lack of analytical confirmation of substances taken and/or the presence of coingestants (including alcohol) that may be contributing to the clinical symptoms and signs. However, combination of these different data sources, through a process known as data triangulation, builds a more robust picture of the acute toxicity of each individual NPS [109].

Mephedrone

User Reports

Information posted on drug user forums indicates a plethora of positive and negative effects, with cathinones often compared to MDMA, amphetamine, and/or cocaine. Positive effects include feelings of empathy, increased energy, improved libido, alertness, euphoria, and better appreciation of music [110]. In the 2012 MixMag survey [111] which involved 7,700 UK respondents, users of mephedrone, cocaine, and MDMA (number not specified) were asked to rate the frequency with

which they experienced certain negative effects associated with mephedrone use: teeth grinding (52%), depression (41%), extreme sweating (36%), overheating (26%), memory loss (24%), agitation (23%), paranoia (17%), severe headache (12%), numb fingers (12%), hallucinations (11%), severe nausea (11%), chest pain (10%), severe tremors (10%), and aggression (4%).

Poisons Information Service Data

The first published data on enquiries to poisons information services was of 150 calls to the Swedish Poisons Centre relating to cathinones, of which two thirds related to mephedrone. The unwanted clinical features were reported as tachycardia (54%), restlessness (37%), mydriasis (25%), hypertension (14%), and anxiety (14%) [112].

The first enquiry to the UK National Poisons Information Service related to mephedrone use was in May 2009. In 131 calls relating to self-reported use of mephedrone or combined mephedrone/alcohol use, the range of unwanted effects reported have been summarized in Table 5 [113]. The frequency of unwanted effects was agitation/aggression (24%), tachycardia (22%), anxiety (15%), confusion or psychosis (14%), chest pain (13%), palpitations (11%), and nausea (11%). Less frequent effects (<10% of enquiries) included dizziness, abdominal pain, mottling of extremities, skin changes/rash, fever, sweating, headache, insomnia, convulsions, myoclonus, and reduced level of consciousness.

Emergency Department Case Reports and Case Series

There have been numerous case reports involving mephedrone; we have used illustrative examples from the published literature to highlight the reported toxicity associated with the use of mephedrone. The first case report of mephedrone use was in a male who used mephedrone by both oral ingestion and intramuscular injection and

Table 5 Adverse events associated with mephedrone use

Physiological system	Adverse events
Cardiovascular	Palpitations, tachycardia, arrhythmias hypertension, hot flushes, Dilated pupils, blurred vision
Neurological	Headaches, light-headedness, dizziness, tremors, convulsions, loss of concentration, memory loss, fatigue, loss of appetite
Psychiatric	Agitation, aggression, paranoia, hallucinations, insomnia, nightmares, anxiety, dysphoria, (post-use) depression, craving, addiction, dependence
Thermoregulation	Variable
Gastro-intestinal	Sore mouth/throat, abdominal pain, nausea, vomiting.
Musculoskeletal	Bruxism (teeth grinding), painful joints.
Respiratory	Nasal irritation, epistaxis, chest pain, respiratory difficulties.
Skin	Skin rash, sweating. Discoloration of extremities

developed symptoms consistent with acute sympathomimetic toxicity (mephedrone concentration in a serum sample was 0.15 mg/l, no other drugs or alcohol were detected) [114]. This has been confirmed in other case reports [115]. There have been specific cardiovascular events such as myocarditis (drug product tested only) [116] and sudden deaths in young people [117]. The following cases do not provide analytical confirmation of mephedrone use but describe other adverse effects out of keeping with simple sympathomimetic toxicity. *Reversible dilated cardiomyopathy*

is described in a 27-year-old male following inhalation and intravenous injection of mephedrone/MDPV a few hours before presentation [118]. Cardiogenic shock ensued; an echocardiogram showed dilated cardiomyopathy with an ejection fraction (EF) of 15–20% and global hypokinesia; this was treated with low dose norepinephrine intravenous infusion for approximately 6 h. At a 20-week follow-up, a repeat echocardiogram showed the EF had improved to 52% with little hypokinesia. A 33-year-old male presented with *methaemoglobinaemia* and symptomatic cyanosis

(SaO₂ 90%, PO₂ 10.4 kPa, MetHb >25% with FiO₂ 21%) after self-reported use of 1 g of “snow” by nasal insufflation (this was believed to be mephedrone by the authors). He was treated with high flow oxygen, improved and was discharged 8 h postarrival. Methylene blue was not used [119]. A 23-year-old male with severe central chest pain and subcutaneous emphysema with self-reported use of inhaled mephedrone 26 h before presentation; a chest x-ray demonstrated a *pneumomediastinum*, but there was no evidence of pneumothorax or esophageal perforation on CT scanning [120]. He was managed conservatively with medical management. There has been another reported case of subcutaneous emphysema related to mephedrone use [121]. A 25-year-old male presented with worsening severe bilateral loin pain with self-reported mephedrone, methamphetamine, diazepam, and cocaine use over a 3-day drug binge. He was diagnosed with *acute kidney injury* (creatinine 654 μ mol/l (8.58 mg/dl), potassium 4.7 mmol/l, bicarbonate 16 mmol/l, creatinine kinase [CK] 1183 iU/l). Renal ultrasound was normal, although a CT angiogram demonstrated diffuse swelling of both kidneys with no evidence of renal infarction. Despite initial medical management, his renal function continued to worsen and he required two sessions of hemodialysis (at day 5 of admission) and subsequently his renal function recovered [122]. A 25-year-old man was admitted with paracetamol overdose requiring NAC infusion, also reported coingestion of 3–4 g of mephedrone. Sixteen hours postingestion he developed *urinary retention*, the urinary catheter was removed 24 h later [123]. A 19-year-old female from Ireland was admitted with alcohol-induced pancreatitis. She had a background of excessive alcohol intake and recurrent pancreatitis. Upon admission she was placed on supportive care, antibiotics, chlordiazepoxide, and multivitamins (amylase 2577 iU/L). On the second day of her admission she had a witnessed convulsive seizure lasting 4 min. There was no focal neurology post event, however, noted to be hypertensive (systolic blood pressure 160 mmHg) and went on to develop subsequent seizures to be treated with levetiracetam. She admitted to snorting

mephedrone prior to admission. An initial CT suggested acute posterior cerebral edema and an urgent MRI brain showed subcortical hyperintensities consistent with a diagnosis of *posterior reversible encephalopathy syndrome* (PRES). She was treated with an intravenous infusion of 1 g/h magnesium sulfate and intravenous labetalol. Magnetic resonance imaging (MRI) 10 days later showed complete resolution of the radiological features [124]. A 22-year-old male presented with tachycardia, profuse sweating, dilated pupils, resting tremor, generalized hyperreflexia, and inducible clonus and was diagnosed with *serotonin syndrome*. The patient had taken 40 capsules from two bags over a 4-h period – a plastic bag labeled “Plant Food” and a brown paper bag labeled “Red Doves” – along with his regular dose of fluoxetine (40 mg) and olanzapine (10 mg). His signs resolved with general supportive care, intravenous fluids, and oral diazepam [103].

A 6-month case series of twenty patients presenting to emergency departments and acute mental health services in Scotland with self-reported mephedrone use identified main adverse effects of severe agitation (70%), psychosis either visual, auditory or tactile (40%), and suicidal ideation (20%) [125]. Up to one in five persons may suffer an unwanted adverse effects [126], but this has been reported to be as high as 56% in various subpopulation surveys [27].

We have previously reported a case series of 72 patients who presented to a Central London emergency department with acute drug toxicity following self-reported use of mephedrone use between January 2009 and June 2010 [127, 128]. The majority of patients were male (89.9%) (mean age 27.8 ± 8.7 years, range 16–54). The main adverse effects documented included agitation (38.9%), palpitations (25%), vomiting (13.9%), chest pain (12.5%), headache (7.2%), and prehospital seizures (6.9%). Additionally, 13.9% had significant hypertension (defined as a systolic blood pressure ≥ 160 mmHg) and tachycardia (defined as a heart rate ≥ 140 mmHg). There were no cases of hyperpyrexia reported (although it should be noted that these cases were collected during the autumn/

winter when hyperpyrexia is less likely to occur due to the cooler ambient air temperature).

There is a second published UK case series of 89 patients who presented to an emergency department in Scotland [115]. Data was reported in detail on the 57 patients with self-reported lone ($n = 30$) or mephedrone and alcohol ($n = 27$) use. Commonly reported clinical features were anxiety or agitation (40.4%), chest pain (24.6%), paresthesiae (24.6%), palpitations (21.1%), dyspnea (17.5%), confusion (14%), collapse (14%), and nondefined oral symptoms (12.3%). As only a range of heart rate and blood pressure were reported, 64–184 bpm and 88–184 mmHg, so while some patients had potentially clinically significant hypertension and tachycardia, it is not possible to determine the frequency of these.

Analytically Confirmed Case Reports

Nonfatal Intoxications

From the previously described case series in London, blood samples were collected for toxicological analysis for mephedrone and/or other drugs [127]. In seven out of nine patients who underwent toxicological analysis for recreational drugs, mephedrone was detected (the remaining two were late presenters at more than 24 h since use); three had other substances detected, including cocaine ($n = 2$) and butylone/MDPV ($n = 1$). Mephedrone was the only drug in 4 and the highest mephedrone concentration in this group was 0.33 mg/L. The most common clinical feature on presentation was agitation ($n = 4$, 57.1%) followed by palpitations ($n = 2$, 28.6%), chest pain ($n = 2$, 28.6%), self-limiting prehospital seizure ($n = 1$, 14.3%), and headache ($n = 1$, 14.3%). Four (57.1%) patients were discharged home from the emergency department/short stay observation unit, two (28.6%) were admitted to general internal medicine ward, and one (14.3%) to the intensive care unit. Overall, six (85.7%) patients survived to discharge from hospital with no long-term sequelae on discharge. The overall mean length of stay following presentation to hospital of those who survived was 12.0 ± 10.3 (range 3.4–26.3) hours. Those

admitted to short stay observation unit required minimal treatment aimed at symptom control (e.g., antiemetics, intravenous fluids). Three (42.9%) patients required the use of benzodiazepines (oral or intravenous) for the management of agitation. One patient died, and this case is discussed below in greater detail.

Mephedrone-Related Deaths

European member states were asked to report to the EMCDDA regarding number of deaths relating to mephedrone use at the time of the European Risk Assessment of mephedrone in 2010 [60]. The UK and Sweden provided cases directly related to mephedrone use with the UK being the only country to provide cases with analytical confirmation at the time of the report. While there were some case reports in the media in other EU nations including Greece and Romania, these countries did not include mephedrone within analytical libraries, and so it was not possible to determine whether it had been implicated in reported deaths. These cases/case series of fatalities from Sweden and UK are listed below.

The first reported death from mephedrone was that of an 18-year-old girl in Sweden who suffered an out of hospital cardiorespiratory arrest, with cerebral edema and marked hyponatremia (120 mmol/L). It is unclear from the reported details whether the cause of the hyponatremia was investigated further [117].

The National Programme on Substance Abuse Deaths (NPSAD) reviewed drug-related deaths in the United Kingdom, the Channel Islands, Isle of Man, Scottish Crime and Drug Enforcement Agency, and the General Register Office for Northern Ireland and identified 128 alleged mephedrone-associated fatalities. Of these, 90 had postmortem confirmation of mephedrone at the time of the report and inquests had been concluded in 69 cases. The mean age of decedents was 28.8 (SD, 11.3) years (range, 14–64 years). Mephedrone was formally included in the cause of death in 36 cases but was only confirmed in eight cases as the sole drug in antemortem/postmortem analysis. Coingestants in other cases

included alcohol ($n = 26$), stimulants [22], sedative/hypnotics [22], opiates/opioids [13], piperazines [13], and remaining synthetic cathinones [13], antidepressants [8], and antipsychotics [5, 129]. A further literature review was conducted by members of the NPSAD group analyzing mephedrone intoxication and subsequent fatality specifically in 16- to 24-year-olds in the UK between 2009 and 2013 [130]. Thirty cases were identified of which the majority were male ($n = 22$, 73%), all had white ethnicity when known (27/30 cases, 90%), half were employed (12/24 cases, 50%), and most (11/13 cases, 85%) had a history of drug use. Approximately half (14/30 cases, 47%) died in a defined residential address (own home or that of a friend/relative) and one quarter (8/30 cases, 27%) in the hospital. Two thirds ($n = 23$, 63%) were accidental poisonings. Other substances were implicated in 60% of deaths; the most common in descending frequency were alcohol, benzodiazepines, piperazines, cocaine, opiates/opioids, amphetamine, and "ecstasy." Postmortem mephedrone blood concentrations were available in 17/30 cases; mephedrone was the only substance detected postmortem in four cases; however, only two of these cases reported blood concentrations (0.190 and 3.300 mg/L; mean 1.745 mg/L). There were eight cases where mephedrone was felt to be solely implicated as cause of death; however, multiple other substances were identified. Six of these cases had recorded concentrations of mephedrone; mean concentration of drug was 1.372 (range 0.070–2.240) mg/L. Finally, the mean concentration of mephedrone in cases where mephedrone was implicated *with* other substances ($n = 9$) as cause of death was expectedly lower, 0.518 (range 0.002 to < 2.000) mg/L.

The only recorded fatality from the London Emergency Department case series [127] involved a 29-year-old male who collapsed in a night club. On arrival in the emergency department, he had a fluctuating conscious level. A CT head scan showed evidence of significant cerebral edema and impending tonsillar herniation. He had hyponatremia ($[Na^+]$ 125 mmol/L); further biochemical testing suggested water intoxication. Following a seizure he deteriorated

further and a repeat CT scan showed tonsillar herniation and so treatment was withdrawn. Antemortem toxicological screening confirmed the presence of mephedrone at a concentration of less than 0.01 mg/L in serum; analysis of powder found with the patient also confirmed the presence of mephedrone. No other recreational drugs were detected on an extended screen of both the powder and biological samples from the patient.

A fatality related to mephedrone use has been reported in another case report from Sweden. A 36-year-old man was arrested by police with acute behavioral disturbance and with self-inflicted wounds obtained by smashing windows. Shortly after the intravenous administration of midazolam and naloxone by medical personnel he had a cardio-respiratory arrest and resuscitation attempts with advanced life support, adrenaline and atropine were unsuccessful. Toxicological analyses as part of the autopsy revealed tablets seized at home contained mephedrone (96 seized at residence, approximately 140 mg per tablet as the hydrochloride) and trace caffeine; further white powder containing cocaine was also seized. Femoral blood was positive for mephedrone (5.1 mg/L) as well as urine (186 mg/L) and stomach contents (1.04 g/L). The coroner concluded the combination of self-inflicted violence had led to substantial blood loss which may have aggravated the sympathomimetic toxicity and severe agitation which was described as a "fatal excited delirium" [131].

A case report from the USA described of a 22-year-old male found collapsed and unresponsive in his living quarters is described. He was unsuccessfully resuscitated in hospital. Urine screening by gas chromatography coupled with mass spectrometry (GC-MS) was positive for 6-acetylmorphine, codeine, morphine, doxylamine, and mephedrone (198 mg/L). Mephedrone was also detected in postmortem blood (0.5 mg/L). The cause of death was recorded as "accidental multiple drug toxicity." A urine sample from a roommate (who confirmed that both he and the deceased had used mephedrone by nasal insufflation, oral ingestion, and intravenous injection) was positive for mephedrone at a concentration of 28.1 mg/L [132].

Busardò et al. performed a literature review in May 2015 and discerned 18 publications regarding deaths with confirmation of mephedrone in post-mortem biological sample(s) [133]. Fourteen cases were male, two were female, and gender was not reported in two cases. Two of the cases within this review have been discussed above to highlight circumstances surrounding some of the deaths [131, 132]. The average age of the decedents was 27.8 years (range: 17–55). Death was attributed to mephedrone intoxication in nine cases (range of mephedrone concentrations: 1.33–22 mg/L), whereas multiple drug toxicity, involving mephedrone was cited as cause of death in six cases (range: 0.04–1.3 mg/L). Coingestants included heroin, MDMA, methadone, benzodiazepines, cocaine, alcohol, and GHB. Implicated contributing factors to final death included a fatal car accident, underlying cardiac fibrosis and atherosclerotic coronary artery disease and severe blood loss from multiple wounds. The authors postulated that mephedrone may have a narrow therapeutic window given blood concentrations detected were similar to those associated with nonfatal recreational use cases.

In general, many case reports/series of cathinones additional detected substances may cloud attribution of clinical features to one recreational drug/class alone and these same problems have been noted in other fatalities [134, 135]. This should alert the clinician to anticipate the presence of other substances when caring for patients with acute recreational drug toxicity. In some instances, these can act synergistically to heighten the anticipated neurotoxic effects as has been seen in rodent models tested with combined use of methamphetamine and mephedrone [90].

MDPV

User Reports

Positive effects as reported on user forums include positive stimulation (mental and physical), euphoria, increased sociability, productivity and motivation, increased mental clarity and creativity, feelings of empathy, and sexual arousal. Negative effects described include trismus, bruxism, anhedonia, loss of appetite, disturbed sleep patterns,

involuntary body movements, confusion, gastrointestinal disturbance, muscle tension and headache, depressed mood, paranoia and anxiety, psychoses and hallucinations, nystagmus, harsh comedown, a process of fiending (re-dosing repeatedly without planning to do so), and excessive agitation and hyperactivity [136].

Poisons Information Service Data

Two US poison centers reported a retrospective case series of patients with exposures to bath salts over January 2010 to February 2011. There were 236 patients, of which 184 were male (78%). Age range was 16–64 years (mean 29 years, SD 9.4). All cases were intentional recreational use. Clinical effects were primarily neurological and cardiovascular and included agitation (194 cases, 82.2%), combative behavior (134, 56.8%), tachycardia (132, 55.9%), hallucinations (94, 39.8%), paranoia (86, 36.4%), confusion (83, 35.2%), myoclonus (45, 19.1%), hypertension (41, 17.3%), chest pain (40, 16.9%), mydriasis (31, 13.1%), creatinine phosphokinase elevations (22, 9.3%), hypokalemia (10, 4.2%), blurred vision (7, 3%), and catatonia (1, 0.4%). There was one death (discussed below). Therapies were primarily sedation and treatment for persistent myoclonus and included the benzodiazepines diazepam, lorazepam, and/or midazolam (125 cases, 53%); the antipsychotics haloperidol and ziprasidone (47, 20%); propofol (10, 4%); and diphenhydramine (2, 1%). The dispositions of patients were: 116 (49%) discharged from the emergency department, 50 (21%) admitted to a critical care unit, 29 (12%) admitted to psychiatric facility, 28 (12%) were lost to follow-up, and 13 (6%) were managed at a nonhealthcare facility. MDPV was detected in the blood/serum of 13 of 17 patients (range 24–241 ng/mL, mean 58 ng/mL) by GC/MS; four samples had no drug detected, but all of these reported last use of bath salts more than 20 h prior to presentation. Three of five patients had MDPV detected in urine (range 34–1386 ng/mL, mean 856 ng/mL). No other cathinones were detected in the tested cohort; no other drugs screen results were recorded [45].

A retrospective review of self-reported synthetic cathinone use was conducted at a poisons

information center in Paris over a 2-year period (2011–2012). Twenty-one cases were identified. Analytical confirmation was performed in only four cases; MDPV metabolites ($n = 2$), methylone ($n = 1$), and alpha-pyrrolidinovallero-phenone (α PVP) ($n = 1$) [137]. Users were mostly men ($n = 20$), with mean age of 38 years (26–53 years). Interestingly, synthetic cathinones were most commonly administered by intravenous injection ($n = 15$, 71%), particularly among the MSM community attending gay sex parties. Fourteen cases presented with psychiatric disorders: psychotic symptoms (52%), agitation (38%), anxiety (33%), suicidal ideas (24%) or attempt (9.5%), and acute satyriasis (9.5%); hence the main reasons for hospital admission were both psychiatric and addiction disorders (62%). Somatic complications were described in 11 cases and included headache (4.8%), tachycardia (14.3%), confusional states (14.3%), rhabdomyolysis (9.5%), with renal failure or serotonin syndrome (4.8%).

A retrospective review of Carolinas Poison Center records was performed regarding “bath salts” or “plant food” exposure from January 2010 to December 2011. Of the 486 calls, 409 cases reported human exposures of which 277 were male (67.7%) with mean age of 28.8 years (21 months–68 years range). The most common clinical effects reported were tachycardia (218 cases, 53.3%), agitated/irritable (206, 50.4%), hallucination and/or delusions (109, 26.7%), and hypertension (103, 25.2%). Three cases involved MDPV use and this was analytically confirmed; there were two associated deaths [138].

Forensic Data from Traffic Offenses

An alternative source of data includes forensic traffic studies regarding drivers arrested for driving under the influence of drugs (DUID). A study from Denmark in 2011 [139] addressed the detection of novel recreational drugs in a cohort of 1,791 cases. Of these 1,335 cases were tested and police revealed 992 cases (74%) were positive for one or more traffic-relevant drugs above the Danish legal limits. Amphetamine and cocaine were most frequently detected (in 383 (28.3%)

and 335 (25.1%) samples, respectively) as well as various benzodiazepines. Nineteen less common drugs were detected: buprenorphine ($n = 7$), butylone ($n = 2$), cathine ($n = 10$), fentanyl ($n = 5$), lysergic acid diethylamide ($n = 1$), *m*-chlorophenylpiperazine, MDPV ($n = 3$), mephedrone ($n = 3$), 4'-methylamphetamine ($n = 3$), *p*-fluoroamphetamine ($n = 5$), and *p*-methoxy-*N*-methylamphetamine. In another report from Finland [140], data was presented on drivers arrested for DUID in 2010 (it is likely that some individuals were included in both this paper and the paper described above as there is overlap between the study periods). A total of 4532 samples were analyzed and 219 (4.8%) were found to contain MDPV at a median concentration of 0.06 mg/L (maximum concentration 8.4 mg/L). Of the MDPV-positive cases, most were male (89%), and MDPV was co-detected with amphetamine (79%) and benzodiazepines (76%); this combination was seen in 63% of the MDPV-positive cases.

Emergency Department Case Reports and Case Series

The first report on the possible use of MDPV appeared in 2007 [141]. Subsequently, there have been many published cases regarding associated complications of MDPV use. Like mephedrone, these vary from organ-specific complications to complete multisystem failure. We have used illustrative examples from the published literature to highlight the reported toxicity associated with the use of MDPV, the spectrum of complications and subsequent management strategies. A 26-year-old man presented with nasal insufflation of 12 g of bath salts, believed to be MDPV, daily for 7 days. On first presentation he displayed stimulant toxicity (described as agitated, confused, tachycardic, and hypertensive) but these settled with antipsychotics (not specified). Admission CK was 2,700 iU/L which increased to 6,013 iU/L with a creatinine of 194.4 micromol/L (2.2 mg/dL) (timing of this result within the 3-day admission was unspecified). The *acute kidney injury* (AKI) was treated conservatively with intravenous fluids for 24 h and he was discharged home on day 3. He

represented 5 days later post a further binge; creatinine peaked to 406.6 micromol/L (4.6 mg/dL) on day 3 of the second admission. Renal ultrasound showed normal-sized kidneys with no obstruction, and urinalysis was positive for protein only. Intravenous normal saline (0.9% sodium chloride) solution was administered for approximately 72 h. AKI was thought to be most likely due to acute tubular necrosis. Urine and serum drug screen results were negative but actual techniques are not described [142].

A case series described four patients with severe cardiopulmonary and neurologic effects. Two 32-year-old women presented to the emergency department shortly after insufflating bath salts. Both complained of palpitations, chest pressure, and dyspnea. One demonstrated *parkinsonian-type features* including resting tremor and bradykinesia as well as ECG changes. Both had positive urine MDPV at concentrations of 0.1 mcg/mL and 0.52 mcg/mL, respectively. The third patient was a 35-year-old man who presented to the emergency department complaining of a rapid heart rate and shortness of breath after snorting bath salts. His urine was positive for MDPV with a level of less than 0.05 mcg/mL [143]. The remaining case resulted in suicide which is referred to below.

The STRIDA project conducted by the Swedish Poisons Information Centre (SPC) and the Karolinska University Laboratory cooperates in monitoring national trends in acute poisonings with novel psychoactive agents [144]. In the first 9 months of 2012, prospective analysis for MDPV in suspected cases in blood/urine led to detection of 86 positive samples. In 17 of these cases symptoms were severe (Poisoning Severity Score 3). Symptoms/signs ranged from excessive agitation, psychosis, sympathetic stimulation (hyperthermia, hypertension, tachycardia), myocardial infarction, rhabdomyolysis, and renal failure. A few patients required prolonged sedative therapy (several days, no further details given). Lindeman et al. (most likely report on a subset of data highlighted in the case series by Bäckberg et al.) [145] conducted a retrospective study of a nonrandomized subset of patients that presented to a hospital with suspected MDPV outbreak

between April and May 2012 in Västerås, Sweden (population 110,000). Forty-five patients were identified with stimulant toxicity (MDPV was suspected in 82% of cases in 2012) and the number of patients treated in intensive care rose from a total of 2 in 2010–11 to 10 in 2012, and the number of intensive care unit (ICU) days from 2 to 45. Seventeen of the 45 patients underwent liquid chromatography (LC)-MS/MS analysis of which 13 (76%) tested positive for MDPV. Sixty percent of the 95% of patients with suspected/confirmed MDPV use were chronic drug users and Hepatitis C virus positive.

A study was conducted using data supplied to the Pavia Poison Centre (PPC) from Emergency Departments in Italy [146]. All consecutive cases were referred to the PPC (January 2010–October 2011) for suspected/confirmed substances of new recreational drug poisoning and analysis. In 52/192 (27%) new recreational drugs of abuse (NeDA) were declared; 7 per cent of patients were unable to report the substances taken. Ethanol intoxication and body packers were excluded. The most common clinical manifestations were agitation (42%), tachycardia (37%), coma (22%), mydriasis (19%), gastrointestinal discomfort (18%), and hallucinations (14%); two fatal cases were registered. Laboratory investigations were performed in 94% of cases (181/192); 70% of biological samples/products were delivered to PPC. The NeDA identified were: MDMA ($n = 25$), synthetic-cannabinoids ($n = 17$), ketamine ($n = 16$), GHB/GBL ($n = 6$), caffeine ($n = 6$), atropine-scopolamine ($n = 6$), butylone ($n = 2$), MDPV ($n = 1$), harmine/dimethyltryptamine ($n = 1$), methylenedioxymphetamine (MDA) ($n = 1$), and 4-Methylethcathinone (4-MEC) ($n = 1$).

There were 524 nonfatal intoxications (of note, Sweden reported 487 of these cases) associated with MDPV use reported by Member States to the EMCDDA at the time of the European Risk Assessment of MDPV in 2014 [71]. Of these, six Member States have reported a total of 110 analytically confirmed cases: Sweden [98], Italy [3], France [4], Belgium [2], Greece [1], and Ireland [1]. In Belgium, MDPV as well as traces of cocaine and amphetamines was detected in the

urine samples (not quantified) of two patients. They both reported visual and auditory hallucinations, paranoia, and were aggressive. They were treated with antipsychotics and their status returned to normal after 3–4 days. France reported four analytically confirmed cases. In one case, police brought a man to the emergency department with an acute delirium (agitation, hallucinations) as well as rhabdomyolysis, tachycardia, hypotension, and acute renal failure; cannabis and pyrovalerone were detected. In the second case, a patient suffered paranoid psychosis post nasal and oral use of MDPV. The clinical features reported were tachycardia, mydriasis, hypertension, agitation, profuse sweating, tremor, and rhabdomyolysis. MDPV (366 ng/mL) and methylone (4400 ng/mL) were detected. The third case was similar to this. Finally, a 39-year-old male presented to hospital after injecting MDPV and using 4-MEC (route not specified). He had abnormal movements, trismus, profuse sweating, visual disorders, insomnia, anorexia, and vertigo. He also reported dysuria, which lasted 24 h; no further details were reported. Greece reported a case of a 47-year-old male who was intubated after sudden loss of consciousness soon after oral consumption of MDPV. He was admitted to the ICU and treated for subsequent multiorgan failure. MDPV was confirmed in his urine. Ireland reported a case of young man who presented with acute psychosis and subsequently developed hepatic failure following ingestion of butylone and MDPV. Further details are described below, taken from the academic study that was performed in this case. Italy reported three analytically confirmed nonfatal intoxications. A 20-year-old male was admitted to hospital very agitated with tachycardia (heart rate 115 bpm). MDPV was found in urine (14 mg/L) and butylone (concentration not reported). The patient was treated with benzodiazepines and discharged 2 days later. The second case, a 38-years-old male, presented at the emergency department with agitation, mild tachycardia (HR 105 bpm), and visual/auditory hallucinations. MDPV was detected in blood (12 mg/L) and urine (17 mg/L). The final case, a 27-year-old male suffering from agitation, confusion, and anxiety, was taken to hospital by his father. The

patient reported having taken intravenous MDPV for last 3–4 days and benzodiazepines. Analysis of the patient's urine revealed MDPV (55 µg/L), alprazolam (113.79 µg/L), and hydroxylalprazolam (103.59 µg/L).

A retrospective multicenter case series of patients with synthetic cathinone abuse was conducted using the national clinical toxicology database (Toxic) in the USA. Twenty-three cases fit inclusion criteria and had MDPV detected in either blood or urine. Eighty-three percent were male and 74% had used it recreationally. The most common route was nasal insufflation (8 cases, 34.8%), although there were patients who ingested (3, 13%), injected (2, 8.7%), or inhaled MDPV (2, 8.7%) as well. The most common reported clinical effects were tachycardia (74%), agitation (65%), and sympathomimetic syndrome (65%). Nine (39.1%) patients had a heart rate >140 bpm, five (21.7%) had a systolic blood pressure between 161 and 180 mmHg, four had a diastolic blood pressure >100 mmHg, and two (8.6%) had a temperature >38.9 °C. The toxidromes noted included sympathomimetic (15 patients, 65.2%), sedative (3, 8.7%), anticholinergic (1, 4.3%), and unknown (5, 17.4%). Within the first 4 h of presentation, 19 of the patients received benzodiazepine therapy which included lorazepam (13 patients), lorazepam and midazolam [4], midazolam [1], or diazepam [1]. Five patients treated with antipsychotic (haloperidol 4 patients, dose range 2.5–5 mg; 1 patient ziprasidone 20 mg). Five patients were given a paralytic. Vecuronium or rocuronium were both used in two patients, and succinylcholine was given in one patient. One patient who was treated with a paralytic and was not treated with benzodiazepines received propofol and etomidate. None of the patients treated with a paralytic were treated with an antipsychotic. Complications reported included myocardial infarction (3 patients, 13%) and intubation (7, 30.4%); there were no reported seizures or stroke. Cardiac arrhythmia (excluding sinus tachycardia) included bradycardia (2, 8.7%) and supraventricular tachycardia (1, 4.3%). Twenty patients were admitted to Intensive Care (87%). Of those admitted, six had quantitative concentrations of

MDPV – blood concentrations varied from <10 to 89 ng/mL. Urine concentrations varied from 120 ng/mL to 3100 ng/mL. Median hospital stay of 2 days (range 0–20), and ICU length of stay of 1 day (range 1–12). Final disposition was home in 14 patients (60.9%), psychiatric unit (7, 30.4%), jail (1, 4.3%), and death (1, 4.3%) [147].

Further severe cases of multiorgan involvement and recovery as well as specific complications of serotonin syndrome and compartment syndrome have been reported. A 25-year-old man presented with unusual behavior, agitation, and essentially sympathomimetic syndrome (mydriasis, BP 148/66 mmHg, HR 175 beats/min, T 41.3 °C) injecting “bath salts.” He was intubated (Rapid Sequence Intubation drugs: midazolam 2 mg, etomidate 20 mg, and succinylcholine 120 mg) and actively cooled (application of ice packs to the axilla and cooling blankets). Over 2 days he developed multiorgan failure: acute kidney injury (creatinine 901.7 micromol/L, 10.2 mg/dL), fulminant hepatic failure (AST 16,688 U/L, ALT 9,085 U/L), disseminated intravascular coagulation (INR > 9.3, platelets 16,000/microL), and rhabdomyolysis (creatinine kinase 235,377 iU/L). He required continuous renal replacement therapy followed by hemodialysis because of anuric renal failure. He was extubated on hospital day 9, and his mental status normalized by hospital day 13. Length of hospital stay was 18 days. Urine from the day of admission tested positive for MDPV at a concentration of 140 ng/mL with high performance liquid chromatography/tandem mass spectrometry. [148].

A 37-year-old male with a history of a right nephrectomy (secondary to trauma) ingested an unknown quantity of “bath salts” approximately 4 h prior to seeking medical care. He was found with severe agitation and tachycardia (HR 153 beats per minute), tachypnea (RR 50 breaths per minute), and fever (T 39 °C). Initial tests included the following concentrations: sodium 165 mmol/L, chloride 114 mmol/L, CO₂ 18 mmol/L, creatinine 548 µmol/L (new, 6.2 mg/dL), and AST/ALT 863/514 IU/L, CK was 90,168 IU/L. He was intubated and sent to ICU and possibly extubated within 24 h later, although this is not clear. Approximately 12 h later, the

CK increased > 350,000 IU/L and he was started on hemodialysis and subsequently had necrotic muscle from the deep erectors which was resected. A urine drug screen via GC-MS confirmed the presence of caffeine, hydrocodone, MDPV, and propofol. Serum MDPV (via LC-MS/MS) 7 h after first seeking medical care was 120 ng/mL and 89 ng/mL after 10 h. Five months later, the patient remained in renal failure on hemodialysis [149].

A 41-year-old woman met Hunter Criteria for serotonin syndrome after use of bath salts for 2 days preadmission. She was intubated for active cooling. Serotonin syndrome was perhaps induced by in-hospital fentanyl use while unwell, which was ceased at recognition at 24–48 h. The patient had prolonged clinical effects in spite of cyproheptadine use (8 days) with return of clonus when the cyproheptadine was discontinued. After extubation, she admitted to taking bath salts by insufflation but denied coingestants or resumption of her previous alcohol abuse. Her urine MDPV concentration was 3,100 ng/mL (detection limit 100 ng/mL). The comprehensive drug panel result was positive for lorazepam, midazolam, acetaminophen, diphenhydramine, lidocaine, ibuprofen, zolpidem, caffeine, and nicotine. Lorazepam, midazolam, acetaminophen, and diphenhydramine were administered at the referral hospital. No documentation of lidocaine administration is available. No amphetamines, antidepressants, or other serotonergic agents were detected [150].

Lastly, there are many cases of neuropsychiatric complaints/severe agitation as well as suicidal/homicidal ideation [71]. A 19-year-old male presented to an ED in the USA with auditory and visual hallucinations which had begun several hours prior to his presentation and after smoking an Internet-purchased product; he stated that voices were urging him to kill unspecified people and someone was trying to steal his thoughts [151]. The psychosis resolved within 24 h in in-patient psychiatric unit, he was treated with promethazine and risperidone. A urine toxicology screen detected MDPV, caffeine, cotinine (nicotine metabolite), and promethazine. A 23-year-old male with prior psychiatric history was seen in the emergency department for bizarre behavior,

suicidal ideation, and hallucinations; he stated snakes were crawling on him and in his bed. He had insufflated 1 g of bath salts 30–60 min prior to presentation. He appeared diaphoretic with mydriasis with a mild tachycardia (BP 133/68, HR 109 bpm, temperature 36.9 °C, RR 21 with 100% oxygen saturations on room air). A total of 6 mg lorazepam and 2.4 mg of droperidol was given intravenously. He had a history of being prescribed various antipsychotics/benzodiazepines in the past (quetiapine, lithium, aripiprazole, valproic acid, and clonazepam). However, he had negative testing for lithium and valproic acid. His symptoms resolved 5 h post sedation. Serum and urine contained MDPV (186 ng/ml, 136 ng/ml, respectively), flephedrone (346 ng/ml, 257 ng/ml, respectively), and caffeine (387 ng/ml, 367 ng/ml, respectively) [152]. Various drugs have been used to treat similar symptoms including benzodiazepines, ketamine, haloperidol as well as chlorpromazine [152, 153].

MDPV-Related Deaths

There have been multiple reports of MDPV-associated fatalities – we refer the reader to EMCDDA and World Health Organization technical reports for MDPV for a complete discussion of cases with both analytical and nonanalytical confirmation [68, 71]. Below we have discussed representative fatal cases with more detailed discussion of the clinical course and cause(s) of death highlighted.

The first reported death in the literature involved a 40-year-old male who self-reported injection and snorting “bath salts” containing MDPV and suffered from the following complications: agitation, aggression, and PEA cardiac arrest with subsequent multiorgan failure due to hyperthermia (T 40.7 °C). Secondary rhabdomyolysis, coagulopathy, acidosis, and anoxic brain injury ensued. An electronic control device had been discharged prehospital on three occasions to overpower the patient by police on scene. Standard advanced cardiac life support measures were initiated. In spite of vasopressor therapy and intravenous fluid

resuscitation – dopamine (20 microgram/kg/min), phenylephrine (180 microgram/h), norepinephrine was started (4 microgram/min), intravenous normal saline (0.9% sodium chloride) solution (4 L), bicarbonate infusion, hydrocortisone (100 mg IV every 8 h), vasopressin infusion (0.04 units/min), hemofiltration for oliguric renal failure, and blood transfusion for symptomatic disseminated intravascular coagulation – he suffered multiorgan failure (potassium 8.0 mmol/L, creatinine 309 µmol/L (3.5 mg/dL), AST 869 iU/L, ALT 738 iU/L, INR 4.2, and creatinine kinase 14,839 iU/L) and died 42 h after his initial presentation. A number of agents were detected on toxicological analysis of patient sera: ethanol (11 mg/dL), salicylate (7.9 mg/dL), acetaminophen (2.9 mg/L), caffeine, cotinine, lidocaine, trimethoprim, and MDPV (urine 670 ng/mL and serum 82 ng/mL) [154].

At the time of the EMCDDA Risk Assessment of MDPV in 2014 a total of 108 deaths in which MDPV had been detected in postmortem biological samples and/or implicated in the cause of death were reported to the Early Warning System (EWS) between September 2009 and August 2013. The member states included Austria (1), Finland (39), France (1), Hungary (1), Ireland (8), Poland (3), Sweden (21), United Kingdom (31), and Norway (1). In addition, deaths have been reported in the scientific literature that occurred within the European Union (17 deaths although there may be overlap with EWS reports) and elsewhere, including the United States (32), and Japan (1). It is likely that other drugs and/or other medical comorbidities or trauma may have contributed to and/or been responsible for death. In the majority of these cases, MDPV was a coingestant with other controlled or novel psychoactive substances and it is hard to differentiate its contribution. Blood MDPV concentrations recorded in these cases ranged from < 0.1 µg/L to 4, 800 mg/L [71].

In April 2011, a 39-year-old man was found with odd behavior, delusional and wandering with minimal clothing. He self-reported “bath salt” use after police escort to the closest emergency

department. After an initial period of observation he became markedly agitated and tachycardic, transferred to ICU for sedation and intubation. He developed ventricular tachycardia, which was treated with amiodarone and defibrillation. Hyperthermia was noted with a peak temperature of 41.7 °C. Within minutes, the patient became bradycardic at 36 beats per minute and, despite atropine and electrocardiac pacing, proceeded to asystole. Further resuscitation efforts were unsuccessful, and he died approximately 12 h after presenting to the ED. Gross autopsy findings were unremarkable. The bile was positive for salicylates, diphenhydramine, MDPV, promethazine, diazepam, and nordiazepam. The heart blood contained 0.1 mg/L diphenhydramine, 0.2 mg/L promethazine, 0.1 mg/L nordiazepam, and 0.7 mg/L MDPV. The peripheral blood MDPV concentration was 1.0 mg/L. The authors concluded MDPV intoxication as the cause, consistent with MDPV-induced excited delirium state [155].

Equally, as observed in the media and reported in coroner case series, self-harm and at-risk behavior without good prior evidence of comorbid mental health illness has occurred including hangings, gunshots, and self-stabbing [156, 157]. A US case series of four patients had reported on one death involving MDPV use. The decedent, a 21-year-old female, was involved in a high-speed chase with the police. A friend of the decedent advised police that she had expressed suicidal ideations and left in her vehicle. During an attempt to retrieve the patient, she sped up to over 100 mph, struck a second car and then came to a stop on a bridge. The decedent was subsequently located in the river below the bridge. The deceased had a history of substance abuse and had been incarcerated several times. The cause of death was drowning, with multiple blunt force injuries listed as a secondary cause of death; the manner of death was accident. The postmortem heart blood analytical findings were: Methylone (0.06 mg/L) and MDPV (0.47 mg/L) [158]. The single fatality from the US poison Center series (reported earlier)

occurred in a 21-year-old male from a self-inflicted gunshot after an active delusional episode witnessed by family members. Quantitative analysis performed on postmortem samples detected MDPV in blood at 170 ng/mL and in urine at 1400 ng/mL [45].

Some deaths are associated with preexisting medical conditions and in some cases imminent death is noted quickly following severe agitation. Kirshner et al. [159] report on two prehospital deaths associated with MDPV intoxication. A 43-year-old man was found dead by police at the edge of a lake. Collateral history from his girlfriend describes erratic behavior and out of personal concerns she had locked herself in the vehicle during his behavior. It was later uncovered that the patient had injected “hookah cleaner” (glass cleaner) purchased from a head shop. Multiple small abrasions and contusions as well as single vessel coronary disease were noted. Urine was negative for drugs of abuse. Blood ethanol concentration was <10 mg/dL and serum MDPV concentration was 160 ng/mL. The second case involved a 37-year-old man who was naked and screaming prior to paramedic attendance as alerted by neighbors. Soon after, he was found to be in asystole and received advance life support and intubation prehospital. He was declared dead after 55 min. His wife confirmed a history of drug abuse and use again of an MDPV-associated “Crystal Clean Hookah & Pipe Cleaner” obtained from a head shop. Autopsy revealed 3-vessel coronary stenosis and rib fractures consistent with CPR. Urine was negative for drugs of abuse. Blood ethanol concentration was <10 mg/dL. MDPV (340 ng/mL), tramadol, and caffeine were detected in the blood. It is unclear if dysrhythmias contributed. There was one case of precipitated diabetic ketoacidosis in a patient with diabetes mellitus [160]. A 46-year-old male was found dead after several days of smoking and intravenously injecting MDPV. He had previous admissions for diabetic ketoacidosis and a significant drug abuse history including zolpidem, hydrocodone, morphine, hydromorphone, black tar heroin, crack cocaine, and methamphetamine.

In the days prior to death according to a friend, the patient was symptomatic with nausea, malaise, vomiting, and had reported uncontrolled glucose concentrations in spite of repeated insulin injections. He reportedly had refused medical attention. At autopsy, quantitation of MDPV concentrations in blood and urine was 39 and 760 ng/mL, respectively. Metoclopramide concentration in blood was 490 ng/mL and vitreous acetone was 106 mg/dL.

Diagnosis

Diagnosis of Mephedrone or MDPV Use

Confirmation that acute sympathomimetic toxicity is likely to be related to the use of mephedrone or MDPV is usually based on self-reported/reported history of use, since analytical screening is often not available in an appropriate time frame. The pattern of acute toxicity as discussed above is very similar to that seen with other sympathomimetic drugs, and it is not possible to differentiate between them clinically.

Cathinones are not tested for on routine toxicology assays. Specialized testing via laboratories that can perform GC-MS and liquid chromatography tandem mass spectrometry techniques has been developed for the analysis of mephedrone and MDPV and some of its metabolites/precursors [77, 161, 162]. Importantly, the mass spectrometry technique does not distinguish between methylmethcathinone isomers; however, nuclear magnetic resonance spectroscopy (NMR) and other techniques allow the isomers to be differentiated [163–165]. There is ongoing work to enable testing in alternative biological matrixes such as saliva, although currently these are mainly used for forensic and/or research purposes [166]. One study has shown that MDPV can be detected using color spot tests such as with testing kits that use reagents including the Marquis reagent and Liebermann's reagent [167]. Importantly, common immunoassay field tests for methamphetamine give false-positive reactions with some cathinone derivatives [168]. Further, MDPV has been reported to cause false-positive

phencyclidine immunoassay results in urine samples [169], and can confound results.

Treatment

Similar to other sympathomimetic drugs, there are no specific cathinone antidotes. Treatment strategies therefore currently draw upon the clinical evidence base for treating other sympathomimetic drugs such as cocaine, amphetamine, methamphetamine, and/or MDMA. The treatment is essentially supportive with specific care directed towards the treatment of unwanted effects in an attempt to prevent medium- to long-term complications and/or death occurring. For asymptomatic patients or those with only mild clinical effects, observation may be required until symptoms/signs subside over several hours or there is evidence of improvement (whichever is shorter). General measures include monitoring of vital signs for rising pulse rate, temperature, or blood pressure. Where patients have specific complications, hyperpyrexia, serotonin syndrome, agitation/aggression/delirium, and/or cardiovascular toxicity, this may require more specific treatment.

Treatment should be directed towards counteracting excessive dopaminergic, norepinephrine, and serotonergic stimulation. To achieve this benzodiazepines are first line (Grade III recommendation). Second-line agents may involve antipsychotics or adjunct sedatives for specific psychiatric symptoms such as agitation with ongoing combativeness; aforementioned cases have used risperidone, intramuscular ketamine, or haloperidol. However, as with other stimulant drugs phenothiazines and butyrophenones should be used with caution since they may exacerbate hyperthermia, QT/QTc prolongation, and possible torsades de points [170, 171].

While rat models demonstrated successful reduction of heart rate and mean arterial blood pressure values with beta blockers [94], given the risk of possible unopposed alpha blockade leading to worsening hypertension, other antihypertensives are recommended (alpha blockers such as phentolamine, nitroglycerin, verapamil,

Table 6 Life-threatening complications associated with cathinone use

Complications
Hyperpyrexia - more likely with ‘aggregate toxicity’
Severe agitation /delirium
Serotonin syndrome
Electrolyte abnormalities
Multi-organ failure e.g. renal failure, hepatotoxicity, DIC
Arrhythmia
Stroke
Self-harm and violence, trauma

Table 7 Indications for ICU admission

Indications
Coma (GCS ≤ 8) and/or clinical deterioration in conscious state requiring airway control and ventilation
Serotonin syndrome
Status epilepticus
Profound hyponatraemia (< 120 mmol/L)
Evidence of end-organ dysfunction e.g. acute renal failure, acute liver failure, DIC
Hyperpyrexia ($\geq 39^{\circ}\text{C}$)

or hydralazine) (Grade III recommendation). Where acute coronary syndromes are suspected, this may require serial troponin measurements, an echocardiogram, and an adopted management approach as is used in cocaine toxicity [172]. Controversy remains about the most efficacious cooling technique in drug-induced hyperpyrexia [173], nevertheless its presence warrants expedient and immediate cooling to avoid multiorgan failure and disseminated intravascular coagulation and may warrant early paralysis and ventilation. There are a few case reports that support the use of

cypheptadine in amphetamine-related toxicity, and extrapolation of these results may provide benefit in the treatment of drug-induced hyperpyrexia with synthetic cathinones [174, 175]. Ultimately, the aggregate clinical features of cardiovascular toxicity, severe agitation/delirium, and hyperpyrexia/serotonin syndrome may warrant rapid sequence intubation and admission to an Intensive Care Unit. Life-threatening complications as documented in case reports and case series have been summarized in Table 6 as well as indications for ICU admission in Table 7.

Prognosis

There are no prospective long-term studies to date regarding the outcomes of patients with intensive care admissions resulting from isolated synthetic cathinone toxicity. Long-term strategies involve consideration for counseling around recreational drug use and assistance given potential for abuse and dependence. There is one report from the UK of a young professional male who developed dependence following 18 months' use of oral, nasal, and rectal mephedrone [176]. He fulfilled the ICD-10 criteria for dependence syndrome, and after in-patient treatment with olanzapine, his symptoms resolved. There are currently no reports of dependence-related MDPV use. Animal models and information from users suggest that there is increased self-administration and repeat dosing related to both mephedrone and MDPV [106]. While this is not likely to be associated with receptor adaptation and physical dependency, there is the potential for psychological dependency developing, which may require appropriate treatment.

Special Populations

Pediatric

There are scant data regarding the acute health effects of cathinones in neonatal and pediatric populations. There is evidence of use of mephedrone in younger age groups. In the aforementioned school survey of 1006 Scottish school and college/university students of those who self-reported using mephedrone on at least one occasion, 56% had reported that they had suffered at least one adverse effect related to its use. The frequency of adverse events described was bruxism (28.3%), paranoia (24.9%), sore nasal passages (24.4%), hot flushes (23.4%), sore mouth/throat (22.9%), nose bleeds (22.4%), suppressed appetite (21.5%), blurred vision (21.0%), palpitations (20.5%), insomnia (19.5%), hallucinations (18.0%), addiction/dependence (17.6%), nausea/

vomiting (17.1%), burns (17.1%), and blue/cold extremities (14.6%) [27].

A retrospective study used data from the Texas Poison Center Network (TPCN) which involves statewide data collection through six poison centers. Synthetic cathinone exposures reported to the TPCN during January 2010–December 2011 were included. Of the 474 calls entered, 362 (76.4%) were exposures. Fifty-one (14.1%) of the patients were between 13 and 19 years of age, 306 (84.5%) greater than or equal to 20 years of age, and five (1.4%) of unknown age. Of the adolescent subset (those aged 13–19-years-old, 31 males and 20 females), the most frequent adverse clinical effects reported were agitation/irritability (22 patients, 43.1%), tachycardia 19, 37.3%), drowsiness/lethargy (7, 13.7%), hallucinations/delusions (5, 9.8%), fever (5, 9.8%), vomiting (5, 9.8%), and hypertension (4, 7.8%). This frequency of unwanted effects was similar to that since in the adult patients, apart from hypertension which was more frequent in the adult patients (72 adults, 23.5%). Approximately 75% of the adolescents were already at or en route to healthcare facility at the time of the poisons center contact [177].

There may be an increased tendency to develop seizures in adolescent populations. The American Association of Poison Control Centers conducted a retrospective review of data regarding synthetic cathinone exposures in children less than 20 years of age from January 1, 2010, to January 31, 2013. There were 1328 adolescent synthetic cathinone exposures identified; seizures complicated 73 (5.5%) of the cases, with 37 (50.7%) of those cases experiencing a single seizure, 29 (39.7%) multiple seizures, and 7 (9.6%) status epilepticus. Fever and acidosis were associated with single seizures, multiple seizures, and status epilepticus. Coingestants were present in 33 (45%) of these cases, most commonly tetrahydrocannabinol, alcohol, and opioids [178].

There is one published case of a neonate born to a mother abusing MDPV. The mother was found unconscious and subsequently the baby was born preterm at 34 weeks with emergency caesarian. The infant was noted to be small-for-gestational-age and was treated for neonatal

abstinence syndrome with enteral morphine. MDPV was detected in infant blood, urine, and cord blood; however, the mother was also positive for opiate metabolites and THC [179].

Key Summary Points

1. Synthetic cathinones are a heterogeneous group of psychoactive drugs that result from differing amphetamine-related structures.
2. Most likely modulate monoamine transporters resulting in various combinations of SERT, NET or DAT interference and various monoamine concentrations at synapse.
3. Broadly, synthetic cathinones result in sympathomimetic and /or serotonergic toxicity, however, must be considered as unique entities and on a case by case basis.
4. Since acute toxicity can be life-threatening, prompt recognition and management is warranted and in the absence of human studies relies on published data on the management of other stimulant toxicity classes such as methamphetamine, amphetamine, and cocaine.

Cocaine has been used for thousands of years for its recognized medicinal properties and for its personally gratifying qualities. The first archeological finding of human use of coca leaves dates back to 3000 b.c. among pre-Colombian Andean societies [1]. The leaves were chewed by chasquis (on-foot mail carriers of the Incan empire) to decrease fatigue and enhance endurance as they delivered royal messages by running from town to town.

Chewing the coca leaf was the preferred method of use until Niemann isolated cocaine in 1859. In the late 1800s, Freud advocated the use of cocaine for many ailments, including the treatment of opioid addiction. During this same period, the renowned John Hopkins' surgeon Halsted reported the local anesthetic effects of cocaine. By the end of the nineteenth century, cocaine became widely used in various medicinal pastes and remedies [2]. It was the main active ingredient in the soft drink Coca-Cola until 1903 [1]. As accounts of addiction multiplied, legislation was enacted that curtailed its use although cocaine was still sold over-the-counter in the USA until 1916. Cocaine continues to be a Schedule II drug in the USA with limited use especially in otorhinolaryngological interventions including in the UK and USA [3–5].

Although a resurgence of cocaine use in the USA occurred in the 1970s, use leveled off until 1983, when “crack” appeared, providing a fast and inexpensive method of self-administration. By 1985, the US National Household Survey on

Drug Abuse from the US National Institute on Drug Abuse estimated that 25 to 40 million Americans had used cocaine at some time in their lives (1.5 million of whom were first-time cocaine users) [6]. Cocaine use reached epidemic proportions in the mid-1980s, when it was reported to be the most frequent cause of illicit drug-related visits to emergency departments [7]. In the last 15 years of the twentieth century, the use of the crystallized freebase form of cocaine became widespread, resulting in many cocaine-related hospitalizations and deaths [8]. Results from the National Institute of Drug Abuse indicate that cocaine use has been declining since 1992 to a plateau of 1.8 million regular users in 1998 (5.7 million in 1985) [9, 10]. This trend continued during the first decade of the twenty-first century. In 2013, it was reported that there were 1.5 million current cocaine users, aged 12 or older (0.6% of the population) and an estimate of 601,000 persons who had used cocaine for the first time within the past 12 months in the USA [11]. Also for 2013, an estimated 3.1 million European adults had used cocaine in the previous year (0.9% the population), with higher use in the south and west of Europe. Especially high prevalence of use was reported in the UK and Spain, though a decline in use has been reported since peaking in 2008 [12]. Despite the decline, the incidence of cocaine-related deaths in the USA increased by 14% from 1992 to 1995 [8, 13]. Cocaine continues to be the most commonly illicit drug of abuse involved in drug-related ED visits in the USA per year as reported by the Drug Abuse Warning Network, with 162.1 visits per 100,000 population in 2013 [14]. European data from the European Monitoring Centre for Drugs and Drug Addiction report on cocaine use health emergencies portrays a similarly high burden on emergency services in European countries, especially in the UK and Spain although the lack of systematic data collection limits comparison [15]. The United Nations Office on Drugs and Crime 2015 World Drug Report data reflects that the use of cocaine as a recreational drug is concentrated in North and South America (especially Brazil), Europe, and to a more limited extent Oceania, despite recent declines in demand but that there

is emerging use in areas of Southern and Western Africa, as well as in Asia [16].

Cocaine toxicity involves all of the body's organ systems. Its use brings patients to the hospital with a variety of clinical features. Complications include medical, psychiatric, and surgical emergencies. In 1995 in the USA, the estimated health-care cost of patients with myocardial ischemia alone secondary to cocaine was greater than \$80 million [17]. A retrospective study reported 1.1% incidence of positive urine screens for cocaine among all hospitalized non-newborn patients during a 12-month period. These patients were predominantly young (average age 31.8 years) crack users and required admission to the intensive care unit 20% of the time [9]. An understanding of cocaine's pharmacology and its pathophysiology is beneficial in identifying and treating patients with the highest risks of complications.

Cocaine Chemistry

The natural tropane alkaloid cocaine is extracted from the leaves of the plant *Erythroxylum coca*. Coca paste is obtained by alkaline extraction of the leaves, using ammonia and organic solvents. The active cocaine alkaloids are contained within the organic phase of the extraction medium, which is then treated with hydrochloric acid to create the water-soluble cocaine hydrochloride (HCl) salt. Cocaine hydrochloride (Fig. 1), often referred to as "powder cocaine," is used intranasally and intravenously. This salt cannot be smoked, as it undergoes pyrolysis at the temperatures required for vaporization [18].

Fig. 1 Chemical structure of the salt cocaine hydrochloride (HCl). When the hydrochloride salt is treated with base, the hydrochloride is removed, leaving cocaine in the alkaloid ("freebase") form

In order to be smoked, cocaine hydrochloride is converted back to its base (non-salt) form, called “crack” or “freebase” cocaine. To convert cocaine hydrochloride to crack, the hydrochloride salt is heated in sodium bicarbonate or ammonia, creating a hard crystallized substance. This crystallized base of cocaine is called “crack” because a popping or cracking sound is often heard when it is smoked. Another process called *freebasing* also gives rise to smokable alkaloidal cocaine. First, the cocaine hydrochloride salt is dissolved in water mixed with an alkaline substance. The base alkaloid is then extracted into ether or another organic solvent, which is separated from the aqueous layer. The final product is obtained by evaporation of the organic phase. This final extraction is hazardous as many of the solvents used are volatile and flammable. Facial and tracheal burn injuries are reported in freebase cocaine users, and fires in clandestine laboratories during the production process have been reported [19]. For the sake of simplicity, in this text all alkaloidal forms of cocaine will be referred to as crack.

Pathophysiology of Cocaine Effects

Pharmacokinetics

Cocaine is absorbed rapidly from all mucous membranes, including the respiratory, gastrointestinal, and genitourinary tracts, giving rise to multiple potential routes of abuse [20]. Its onset of action is almost immediate from the intravenous or inhalational route (0.5–2 min) and is delayed 20–30 min after nasal insufflation [21, 22]. Gastrointestinal absorption is delayed further by a minimum of 90 min. The duration of effect is related closely to the onset of action, with intravenous and inhalational exposure lasting approximately 30 min, nasal insufflation lasting about 1 h, and gastrointestinal use lasting at least 2–3 h (Table 1).

The physiological effects of cocaine are the summation of the effects of the parent compound, its metabolites, and their respective pharmacodynamics. Once absorbed, less than 5% of the parent

Table 1 Toxicokinetic parameters of cocaine

Method of use	Peak onset of symptoms (min)	Duration of effect (hr)
Oral (cocaine HCl)	60–90	>3
Intranasal (cocaine HCl)	30	1–2
Smoking (freebasing, crack)	0.5–1.0	0.25–0.5
Intravenous (cocaine HCl)	0.5–2.0	0.25–0.5

HCl hydrochloride

compound is cleared in the urine [23]. More than 11 metabolites of cocaine have been described, and some deserve mention. Cocaine is metabolized rapidly by a combination of enzymatic and nonenzymatic hydrolysis [24]. Enzymatic hydrolysis by plasma and liver esterases yields ecgonine methyl ester. Ecgonine methyl ester has mild vasodilating properties and has a plasma half-life of approximately 5 h [25–27]. Decreased plasma cholinesterase activity enhances cocaine toxicity in mice [28]. Similarly, patients with relative plasma cholinesterase deficiency seem to be at increased risk of adverse consequences from cocaine toxicity [29].

Another metabolite, benzoylecgonine, is formed mostly via nonenzymatic (chemical) hydrolysis. Although an enzymatic hydrolysis pathway producing benzoylecgonine is known, it probably accounts for only a small percentage of this metabolite [24]. Benzoylecgonine has potent vasoconstrictive properties, although less than the parent compound. It has a plasma half-life of approximately 8 h [26, 28, 30]. One important fact about benzoylecgonine is that this metabolite is tested in most urine immunoassays. It is detected for 48–72 h after infrequent cocaine use or 3 weeks in high-dose chronic cocaine users [31, 32].

Together, ecgonine methyl ester and benzoylecgonine constitute approximately 85% of cocaine’s metabolism [33]. Less than 10% of cocaine is metabolized by *N*-demethylation mediated by CYP3A4 in the liver, forming norcocaine [34, 35]. This metabolite is highly vasoconstrictive

and in animal models produces clinical effects similar to those of the parent compound [26].

Additionally, in the presence of ethanol, cocaine is transesterified by liver esterases to ethylcocaine, which is also known as cocaethylene [36]. Cocaethylene has a longer half-life (2.5–6 h) than cocaine [35]. In humans, coadministration of cocaine and ethanol produces prolonged euphoria [37]. This metabolite has pharmacologically significant central and peripheral effects that are similar to those of cocaine [38–41]. Additionally, animal studies with cocaethylene show a dose-dependent myocardial depression effect and more potent Na⁺ channel blockade than cocaine [40, 42].

Although some data shows that cocaine purity is on the rise in Western Europe [43], average purity is generally below 50% and on the fall in the USA, with indication that increased cocaine purity may be associated with adverse health-care outcomes [44, 45]. Many adulterants are found in cocaine including some with pharmacological activity (phenacetin, lidocaine, tetracaine, diltiazem, caffeine), most of which have minimal toxic effects but may include seizures and nephrotoxicity [46]. Special mention should be made of levamisole, an antihelminthic agent no longer used in human medicine that recently has been reported worldwide as a cocaine adulterant and is found in up to 69% [47] of cocaine in the USA, in Europe [48, 49], and in 54% of samples of cocaine destined to international trafficking in Brazil [50]. Patients presenting with oropharyngeal symptoms, agranulocytosis, leukoencephalopathy, and vasculitis [47, 51–55] are reported after using levamisole-adulterated cocaine.

Mechanism of Action

Cocaine’s effects derive from its sodium channel blockade and its central and peripheral inhibition of monoamine reuptake. Sodium channel blockade is responsible for cocaine’s local anesthetic effects by inhibiting nerve conduction [56]. The effect is also important in the myocardial conduction system, where it produces quinidine-like

Table 2 Mechanism of action and clinical manifestations of cocaine poisoning

Mechanism	Clinical manifestation
Sodium channel blockade	Local anesthesia
	QRS widening on ECG
	Decreased cardiac muscle contractility
	Respiratory depression
Monoamine reuptake inhibition	
Epinephrine	Tachycardia
Norepinephrine	Hypertension
Dopamine	Psychomotor agitation with attendant elevation in temperature. Reward leading to dependence. Movement disorders

Excitatory amino acids	Seizures
Platelet activation and alterations in plasma thrombogenic constituents	Thrombogenesis

ECG electrocardiogram

(sodium channel-blocking), membrane-stabilizing properties that result in QRS widening and decreased contractility [57–59]. In large doses, sodium channel blockade in the medullary centers produces respiratory depression and sudden death (Table 2).

Cocaine’s second mechanism of action (inhibition of monoamine reuptake) increases the concentrations of norepinephrine, dopamine, serotonin, and excitatory neurotransmitters in the synaptic space [58, 60, 61]. This mechanism is responsible for many of the stimulatory effects on the sympathetic nervous system. Some of the centrally mediated effects are euphoria, psychomotor agitation, and respiratory stimulation.

The increase in synaptic and circulating concentrations of catecholamines stimulates adrenergic nerve terminals, resulting in an increase in sympathetic activity [60]. Typically, sympathetic nervous system stimulation manifests as hypertension, tachycardia, diaphoresis, mydriasis, and hyperthermia. Pressor effects are mediated by

norepinephrine of sympathetic neural origin, whereas tachycardia is secondary to epinephrine derived from the adrenal medulla [60].

Other effects of cocaine are secondary to its dopamine reuptake inhibition. Dopamine D₁/D₅ antagonists attenuate the euphoric effects of cocaine [62]. Administration of cocaine directly into motor centers produces an increase in locomotion that is reversed by coadministration of dopamine antagonists [63]. Restlessness, agitation, and seizures can occur from motor center stimulation after cocaine administration. This psychomotor stimulation after cocaine administration is absent in mice lacking the dopamine transporter [64]. Chronic cocaine use also depletes dopamine from reward centers in the brain. This mechanism is thought to be the basis for its reinforcement and addictive properties [65].

The serotonergic effects of cocaine are unclear. Serotonin modulates certain biologic processes, such as mood, personality, temperature regulation, affect, appetite, motor function, sexual activity, sleep induction, hallucinations, and vasospasm. All of these processes may be affected during chronic cocaine abuse and withdrawal [66].

Cocaine increases excitatory amino acid concentrations in the nucleus accumbens by enhancing dopamine stimulation of the *N*-methyl-D-aspartate (NMDA) receptor [60]. In animal models, NMDA antagonists attenuate the effect of cocaine on the nucleus accumbens [67] and prevent cocaine-induced seizures and death [68].

Cocaine has several hematological actions, which may promote thrombogenesis. Tonga and colleagues [69] first noted an increase in rabbit platelet aggregation and thromboxane production *in vitro*. Similar results of platelet activation are reported in *in vitro* human volunteer studies [70, 71] and in an *in vivo* canine model [72]. Cocaine also alters plasma constituents (increases tissue plasminogen activator type I activity, increases von Willebrand factor) that regulate thrombus formation [73, 74]. An additional direct effect of cocaine on the vascular endothelium causes release of endothelin-1, a potent endogenous vasoconstrictor [75]. Lastly, cocaine induces a transient erythrocytosis, further restricting blood flow. This latter effect is well-described in patients

chewing coca leaf during exercise [76–78]. As a result, intravascular thrombosis after cocaine use occurs in a variety of vascular beds [79–84], both in diseased and nondiseased vessels.

Clinical Presentation

Cocaine toxicity may involve multiple organ systems. Although most patients with acute cocaine-associated toxicity may be managed in the emergency department, some require hospitalization due to catastrophic complications. Most complaints are cardiopulmonary (56.2%), neurologic (39.1%), and psychiatric (36.8%), although multiple systems often are involved (57.5%) [85].

The effects of cocaine on the different organ systems are a combination of the overall intrinsic effect of cocaine on vascular tone and thrombogenicity and the specific physiologic response of the involved organ system. Arterial vasoconstriction and spasm and intravascular thrombosis occur in vascular beds throughout the body [79–84, 86–88]. Some of the clinical manifestations of cocaine-induced vasospasm include cerebral infarction, myocardial infarction, blindness, central retinal artery occlusion, mesenteric ischemia, and renal infarction [82, 83, 89–93]. Secondary effects of cocaine that affect multiple organ systems are hypertension and tachycardia, which increase tissue oxygen demand and further impair organ performance.

Hyperthermia

Cocaine use can result in serious toxic effects and death in part because of hyperthermia. Even relatively low doses of cocaine can elevate core temperature and hamper cardiac reserve [94]. High ambient temperature is associated with a significant increase in mortality from cocaine overdose [95].

Cocaine causes hyperthermia in several ways. It increases psychomotor agitation, which results in increased heat production. As a vasoconstrictor of the peripheral vasculature, cocaine impairs heat dissipation. Additionally, because the

thermoregulatory centers in the hypothalamus are dopamine modulated, cocaine has direct effects on temperature control [96]. Several case reports describe fatal hyperthermia without severe agitation or rhabdomyolysis in cocaine users [97, 98]. This model of hyperthermia as a major cause of acute cocaine fatality is well established in cocaine-poisoned dogs [99]. When ambient temperature increased from -5°C to 5°C (23°F to 41°F) in this animal model, the survival rate decreased from 100% to 57% [99]. Of all vital sign abnormalities, hyperthermia seems to correlate most with fatality.

Neurological Manifestations

Cocaine is a popular illicit drug of abuse because of its stimulatory effects on the central nervous system (CNS). Its use also generates a variety of untoward effects on the CNS. These CNS complications occur with all forms of cocaine administration and include cerebrovascular ischemia and infarction, transient ischemic attacks, subarachnoid hemorrhage, intraparenchymal hemorrhage, seizures, cerebrovascular thrombosis, cerebral vasculitis, migraine headache, anterior spinal artery syndrome, and movement disorders (Table 3) [87, 88, 91, 100–108].

Cerebrovascular Accidents

Cocaine-related strokes were first reported in 1977 [101]. Epidemiological studies clearly support cocaine as a risk factor for stroke, although the magnitude of this association is not easily estimated with available studies [122]. Strokes can be either ischemic or hemorrhagic though limited data shows that the form of cocaine used might have an influence on the predominant etiology. The incidence of ischemic and hemorrhagic strokes secondary to crack cocaine is approximately the same [87], whereas 80% of cocaine HCl-induced strokes are hemorrhagic [88].

Patients with cerebrovascular ischemia or infarction may present with focal lateralizing neurologic deficits. Clinical features in these patients are typical of patients with cerebrovascular

Table 3 Cocaine-induced central nervous system complications

CNS complications	Etiology	References

accidents, with aphasia, hemiplegia, dysarthria, and/or paresthesiae/sensory loss.

Cocaine-induced cerebral hemorrhage may be intraparenchymal or subarachnoid; however, cocaine-positive patients with intracerebral hemorrhage are more likely to have intraventricular hemorrhage, subcortical localization, seizures, and a poorer prognosis [112, 123]. The incidence of neurovascular complications among cocaine-related hospital admissions is low (0.35–3%) [109, 113]. However, autopsy studies of fatal nontraumatic intracranial hemorrhage reported an incidence of cocaine abuse to be 7–59% [124, 125]. Headache is the most common symptom on presentation. Other presenting signs include meningismus, altered mental status, seizures, and focal neurologic deficits [105].

The mechanisms of cocaine-related ischemic strokes are multiple and overlapping and have been related to focal vascular disease. Proposed causes include vasospasm (either pharmacologically induced or secondary to hypertension), thrombosis, and vasculitis. Cerebral vasoconstriction, documented by magnetic resonance angiography, occurs within 15 min of cocaine

administration in asymptomatic human volunteers [126]. In head computed tomography (CT) scan-proven cerebral infarctions, angiography revealed evidence of vasospasm and thrombosis [91]. Biopsy-proven cerebral vasculitis as a cause of ischemic stroke is also rarely reported [100].

Alternatively, acute systemic hypertension as a result of the sympathomimetic effects of cocaine is the proposed mechanism for cocaine-related hemorrhagic strokes. The sudden increase in blood pressure may precipitate the rupture of a preexisting vascular malformation or aneurysm [87]. Arteriography has shown both of these vascular abnormalities in many cases of cocaine-induced subarachnoid hemorrhage and in some cases of intraparenchymal hemorrhage [105, 109, 111, 113]. Patients suffering from aneurysmal subarachnoid hemorrhage after cocaine use have a higher risk of aneurysmal re-rupture and a higher hospital mortality [127].

Although most strokes occur either immediately or within the first 3 h after cocaine use, Levine and associates [87] reported that 18% of strokes occur after an abstinence period of at least 2 days following a period of heavy crack use. Possible explanations for these delayed events are the prolonged half-life of cocaine's metabolites (benzoylecgonine) and cocaine's intrinsic thrombogenic effect.

Seizures

Although seizures are well associated with cocaine use, they are a relatively uncommon presenting feature of emergency department visits and hospitalizations among patients with cocaine-related complaints (2.8–8.4%) [110, 114, 115]. A systematic review of evidence however did not find an association between cocaine and seizure activity [128]. Most cocaine-induced seizures occur as the only manifestation of cocaine toxicity. They are predominantly single, generalized, and tonic-clonic. Approximately 20% are focal in onset. Seizures that are focal or multiple often are associated with acute intracerebral complications [116]. Although some cocaine-induced seizures occur secondary to a large CNS hemorrhage or

infarction, most are not associated with any lasting neurologic deficits [110, 117].

Most cocaine-induced seizures occur within 90 min of use [117]. Similar to cocaine-induced strokes, this corresponds temporally to peak plasma cocaine concentrations [104, 116, 117]. Delayed seizures may be caused by benzoylecgonine because this metabolite is also a potent CNS vasoconstrictor [129].

Cocaine also lowers the seizure threshold and precipitates seizures in patients with known seizure disorders [118]. Patients with a prior history of epilepsy have a higher frequency of cocaine-induced seizures than patients without a history of seizures [116]. Partial or multiple seizures occur more often in patients with prior history of epilepsy [118]. Additionally, animal studies and human case reports suggest seizures “kindle” after habitual cocaine use [116, 117]. This process increases the sensitivity of the brain following repeated doses.

Neuropsychiatric Features

A wide range of neuropsychiatric features are common complaints in cocaine-associated emergency department episodes [85, 119]. These range from anxiety [120] to psychosis [121], including suicidal intent. Agitation and aggression are hallmarks of severe cocaine toxicity and pose a risk to patient and caregiver safety.

Other Neurological Effects

Cocaine induces a variety of movement disorders, which are presumed to be dopaminergic in origin. These movement disorders include dystonia, choreoathetosis (commonly known as *crack dancing*), akathisia, buccolingual dyskinesia (risus sardonius), and exacerbation of Tourette's syndrome. The high incidence of acute dystonic reactions in cocaine-addicted patients treated with antipsychotic medications suggests a dysfunctional dopamine-mediated basal ganglia effect [102].

In addition to the kindling effect, chronic use of cocaine is associated with an increase in cerebral atrophy [130]. Because reward centers in the brain are under control of dopaminergic tone, depletion

of dopaminergic transmission in these areas after repeated administration of cocaine produces a craving for the drug.

Cardiac Manifestations

Cardiac manifestations of cocaine poisoning are common and have been well recognized for years. Most symptoms relating to acute cocaine use suggest a cardiovascular etiology, with 40% of cocaine-related visits to the hospital having chest pain as the leading single presenting symptom [85]. Other symptoms that occur at presentation and could be related to cardiac events include diaphoresis, palpitations, and dyspnea [85, 119]. Because of cocaine's multiple effects on the coronary vasculature, evaluation of patients for myocardial ischemia or infarction is important with any of these presenting symptoms.

Myocardial infarction as a complication of cocaine abuse was first reported in 1982 [131]. It is now well recognized that myocardial infarction occurs with intranasal, intravenous, and inhalational use of cocaine [132]. Retrospective studies of cocaine-associated chest pain reported an incidence of myocardial infarction ranging from 0% to 31%. Subsequent prospective studies indicated that the frequency of infarction defined by creatine kinase-MB fraction (CK-MB) or troponin criteria more likely approximates 0.7–6% [132–136].

The typical patient with cocaine-induced myocardial infarction is a male, 18–52 years old (median age 33 years old) with a history of regular tobacco smoking and frequent cocaine use. The quality of the chest pain is usually atypical of ischemia, and the location of the pain does not predict myocardial infarction [132].

Two thirds of patients with chest pain experience it within 3 h, and 93% have chest pain within 24 h of cocaine use [90, 132, 137]. A greater delay in the onset of symptoms is experienced rarely but has been documented [138]. Myocardial infarction 3 days after cocaine use was reported by Del Aguila and Rosman [139]. Additionally, Holter monitoring detected ECG changes (ST-T changes, ST-segment elevation) up to 6 weeks after an

inpatient detoxification admission in cocaine-addicted patients (in 8/21 patients vs. 1/42 controls) [138].

Cocaine causes myocardial infarction by several mechanisms. Acutely, cocaine use leads to hypertension, tachycardia, and vasoconstriction, all of which increase myocardial oxygen demand. First, an elevation in heart rate and blood pressure increases myocardial workload. More dramatic elevations in blood pressure may intensify the shearing forces in the major vessels, causing aortic dissection and rupture [140–145]. Dissection of coronary arteries has occurred [146, 147]. Second, cocaine causes local vasoconstriction of the coronary vasculature. In human volunteers, this effect occurs within 15 min of cocaine administration, as is well documented by angiography [87]. This arterial vasoconstriction is markedly worse in coronary artery segments previously narrowed by atherosclerosis [148]. In the presence of cocaine and its increased sympathetic activity, the normal coronary vasodilating response to a diminished oxygen supply is overwhelmed.

The vasoconstrictive effects of cocaine are established to be α -adrenergically mediated. Propranolol, a β -adrenergic antagonist, exacerbates coronary narrowing after cocaine infusion, whereas phentolamine, an α -adrenergic antagonist, reverses this effect [149, 150].

Acute and chronic effects of cocaine are associated with its thrombogenicity and ability to accelerate atherosclerosis. Coronary angiography performed in patients after cocaine-associated myocardial infarction often shows intracoronary thrombus and atherosclerotic lesions at different stages of stenosis in any of the coronaries [137, 151, 152]. Autopsy and coronary catheterization reports of chronic cocaine abusers show advanced atherosclerosis despite a young age [90, 145, 153–156]. Additionally, rabbits fed a 0.5% cholesterol diet and injected with cocaine develop atherosclerotic lesions in the aorta [157]. In humans, chronic cocaine use is said to increase the prevalence of aortic atherosclerotic lesions independent of traditional cardiac risk factors [158]. In contrast, more recent studies in symptomatic patients with low to intermediate risk of acute coronary syndromes (ACS) who underwent

coronary computerized tomography angiography have failed to find an association between cocaine use and advanced atherosclerosis. The presence of coronary lesions as measured by the extent of vessel stenosis ($\geq 25\%$, $\geq 50\%$) [159], extent of calcified and noncalcified coronary plaques [160], and coronary calcium scores [159, 161] were not different among patients who use cocaine and those who do not.

Cocaine use also has global cardiac effects that may produce ischemia. Data from both echocardiography and cardiac catheterization reveal that cocaine use depresses myocardial function. Dilated cardiomyopathy is reported with normal coronary arteries in patients with habitual cocaine use [162, 163]. Ventricular angiography showed myocardial dysfunction as measured by worsening hemodynamic parameters in patients infused with cocaine [164]. Left ventricular systolic dysfunction, secondary to cocaine's myocardial depressant effect, presents as congestive heart failure and cardiomyopathy [151, 163]. These cardiovascular hemodynamic changes alter the genetic expression of contractile proteins in cocaine-treated rats [165]. Inflammatory lymphocytic and eosinophilic infiltrates consistent with myocarditis are found in myocardial tissue from some patients with cocaine-related deaths [166, 167]. These anatomic alterations may provide a substrate for reentrant dysrhythmias and other conduction abnormalities.

Cocaine may produce cardiac dysrhythmias in several ways, including direct effects on the conduction system and release of endogenous catecholamines. In low doses, cocaine may result in bradycardia. Higher doses cause all types of tachydysrhythmias, with sinus tachycardia being the most common. Other rhythm disturbances frequently associated with cocaine use are atrial fibrillation, narrow-complex and wide-complex supraventricular tachycardias, ventricular tachycardia and fibrillation, and torsade de pointes [57, 59, 137, 168–170]. Animal models and case reports of wide-complex supraventricular tachycardias suggest that these dysrhythmias resemble those following poisoning from other sodium channel blockers such as type I antidysrhythmic or tricyclic antidepressants. Slowing of phase 0 of

the action potential in cocaine intoxication is secondary to the direct sodium channel-blocking effects of cocaine [171]. Cocaine-induced Brugada-type ECG findings are reported and are also likely related to the sodium channel action of cocaine [172]. Additionally, ventricular dysrhythmias may develop secondary to cocaine-induced ischemia or infarction. Although QT prolongation is common, torsade de pointes is uncommonly reported [168, 173–175]. Numerous reports document sudden prehospital cardiac arrest secondary to cocaine use, which may be related to cocaine ion-channel blockade or secondary to cocaine-mediated ischemia [145, 152, 167, 176].

A rare but devastating cause of chest pain in cocaine users is aortic dissection. In the International Registry of Acute Aortic Dissection of 3584 patients with aortic dissection, 1.8% had documented recent cocaine use, and these patients were relatively younger (47 years old in cocaine positive patients with type A and type B dissections, 61 and 64 years old for cocaine-negative type A and type B, respectively) [177].

Pulmonary Manifestations

The pulmonary complications of cocaine use arise from its pharmacological effects on pulmonary physiology and from the various methods of administering the drug. Cocaine-induced vasoconstriction and platelet aggregation, pulmonary hemorrhage, and pulmonary thrombus can occur. Hemoptysis is reported to occur in 5.7% of habitual smokers of freebase cocaine [178]. Histopathology of fiber-optic bronchoscopic lavage and autopsy reports of acutely cocaine-intoxicated patients reveal diffuse interstitial and alveolar hemorrhage, bronchial arterial constriction, and ischemic damage [179, 180]. Pulmonary infarction is encountered less often [181], mainly because of the dual blood supply to the lungs from the pulmonary and bronchial arteries.

Since the 1990s, habitual smoking of crack has replaced nasal insufflation of cocaine HCl as the most common method of use in the USA likely because of the faster onset and greater intensity of effects achievable with smoking. Each of these

routes of administration is associated with unique pulmonary complications. Thermal burns of the upper airway, including the tongue, epiglottis, vocal cords, and subglottic area, occur after smoking cocaine [182]; this is from inhalation of either hot cocaine or ether used to prepare the alkaloid form of cocaine. Acute respiratory symptoms (cough, black sputum, chest pain, shortness of breath, asthma) [183] occur with high frequency in temporal association with crack smoking.

Functional disorders of the lungs, gas exchange abnormalities, and reactive airway disease also occur commonly [184]. Subsequent pulmonary artery medial hypertrophy occurs in 20% of individuals who chronically abuse cocaine. This condition occurs in the absence of foreign particle embolization and is independent of the dose, frequency, or route of administration [185].

The condition known as “crack lung” that results from inhalation of cocaine is described as pulmonary infiltrates, fever, and bronchospasm. An immunologic etiology of these effects is supported by the findings of eosinophilia, elevated IgE concentrations, and pruritus, all of which resolve with abstinence of drug use [186–188]. These findings suggest that heavy crack smoking produces respiratory tract injury manifested by acute respiratory symptoms and evidence of chronic airflow obstruction in large airways.

Acute pulmonary edema secondary to cocaine use is also encountered due to both cardiogenic and noncardiogenic causes. Noncardiogenic pulmonary edema (acute respiratory distress syndrome) results from either the direct effect of cocaine or adulterants on the pulmonary alveoli and endothelium by increasing their permeability [189].

Barotrauma occurs in individuals who use a Valsalva-type maneuver for rapid absorption of cocaine. There are numerous case reports of patients presenting to the emergency department with pneumomediastinum, pneumothorax, or pneumopericardium. These abnormalities occur secondary to the mechanics of drug administration rather than directly related to cocaine itself [190–197]. A retrospective study that evaluated

patients presenting with spontaneous pneumomediastinum found that 76% of the cases were associated with illicit inhalational drug use. Of these cases, 53% were secondary to cocaine use. Evaluation of the presenting clinical symptoms revealed that 82% of the patients had a complaint of chest pain or shortness of breath or both. The absence of an abnormal physical finding was uncommon: most patients (88%) had subcutaneous emphysema, Hamman’s crunch, or both [195].

Chronic cocaine smokers develop gas diffusion abnormalities at the alveolar-capillary level [178]. The cause of the diffusion defect is consistent with increased lung epithelial permeability secondary to damage to the alveolar-capillary membrane. This crack-related lung injury, reflected by abnormally rapid ^{99m}Tc -DTPA (diethylenetriamine pentaacetate aerosol) lung clearance, is at least partially reversible after a 3-month period of abstinence from smoking crack [198].

Gastrointestinal Manifestations

Gastric and mesenteric arteries have abundant α -adrenergic receptors [199], which constrict in response to cocaine. The intensity and location of vasoconstriction determine the extent of injury. Acute gastrointestinal ischemia occurs with all routes of cocaine administration. Patients who smuggle cocaine in the gastrointestinal tract in wrapped packets can suffer from local effects (obstruction, perforation), but the most catastrophic outcomes are a consequence of systemic toxicity due to ruptured packets [200, 201].

Pathophysiologically, cocaine’s decrease in mesenteric blood flow results in bowel edema, ulceration, and ultimately necrosis. Perforation of the duodenum, jejunum, ileum, and colon are all well described [82, 202–205]. Large intestinal ischemia from localized vasoconstriction may present as colitis [82, 83].

Kram and colleagues [204] compared patients with cocaine-induced gastroduodenal ulceration and perforations with patients with perforations and ulcerations secondary to peptic

gastroduodenal ulcer disease. These investigators reported the former patients to be younger, to have no prior history of peptic ulcer disease, and to differ in the location of their lesion. In cocaine users, the ulcerations occur in the first portion of the duodenum, the prepyloric region of the stomach, the pyloric canal, or the greater curvature of the stomach. In contrast, in patients with peptic ulcer disease, ulcers primarily develop in the duodenal bulb [206].

Cocaine is also associated with splenic infarction [207] and with abnormal spleen hemodynamics [208]. Cocaine administered intravenously to volunteers caused a 25% reduction in spleen volume and altered hematologic parameters (increase in hemoglobin concentrations, hematocrit values, and red blood cell counts) [209].

Renal Manifestations

The renal effects of cocaine may be related primarily to direct vasoconstriction of the renal vasculature or secondarily to systemic toxicity with resultant hyperthermia, seizures, and rhabdomyolysis. Cocaine-induced acute renal infarction is reported rarely with one case demonstrating renal artery thrombosis and embolization [84, 92]. In this setting, patients may present with flank or upper abdominal pain, nausea, vomiting, microscopic or gross hematuria, and proteinuria. The mechanism may be a combination of spasm of the renal vasculature and thrombogenesis from cocaine's direct effect on platelets and prostaglandins. Kidney biopsy findings demonstrate fibrinoid necrosis involving the interlobular arterioles, similar to those found in scleroderma [210, 211]. It is thought that these changes cause accelerated and/or malignant hypertension inducing acute kidney injury (AKI) ultimately leading to chronic kidney disease. Although rare, other pathological changes found on kidney biopsies are vasculitic in nature. They include Henoch-Schönlein purpura and necrotizing vasculitis with immunoglobulin A, immunoglobulin M, and C3 deposits in the mesangium [212], thrombotic microangiopathy [213], and pregnancy-related AKI mimicking

preeclampsia [214]. There are rare reports of interstitial nephritis-induced AKI [215] and anti-glomerular basement membrane glomerulonephritis [216]. In many patients, kidney function returned to normal while others became dialysis dependent.

Rhabdomyolysis

Cocaine produces both atraumatic and traumatic rhabdomyolysis that may lead to AKI [217, 218]. In large doses, cocaine has a direct toxic effect on skeletal muscle, causing myofibrillar degeneration. Also, muscle ischemia from vasoconstriction may predispose to rhabdomyolysis. Traumatic rhabdomyolysis occurs as cocaine impairs behavioral responses to the environment, causes agitation, and induces seizures.

A prospective case series of patients presenting to the emergency department with complaints related to cocaine use showed a high incidence of cocaine-associated rhabdomyolysis. Of all cocaine users, 24% had rhabdomyolysis, defined by an elevation of creatine kinase (CK) of more than fivefold above the mean (>1000 U/L; >17 μ kat/L). The same study found that only 13% of the patients presenting with rhabdomyolysis experienced any of the classic signs or symptoms (nausea, vomiting, myalgias, muscle swelling and tenderness, weakness) [219]. Other causes of rhabdomyolysis also present without any signs and symptoms, which emphasizes the need for laboratory evaluation when establishing this diagnosis.

A retrospective study of patients with cocaine-associated rhabdomyolysis (defined as CK above 500 U/L or 8.3 μ kat/L) showed that patients at highest risk for complications (acute kidney injury, hypocalcemia, hyperphosphatemia) from rhabdomyolysis were patients presenting with severe signs of cocaine toxicity (altered mental state, hyperthermia, hypotension or hypertension, seizures, leukocytosis or symptomatic arrhythmia), having longer hospital stays than those with milder signs of toxicity (chest pain, anxiety, diaphoresis, dyspnea, tachycardia). Those with acute cocaine toxicity who had admission serum

Table 4 Causes of cocaine-associated acute kidney injury

Clinical presentation	Etiology	References
Acute kidney injury	Rhabdomyolysis	[98, 217–220]
	Vasculitis, scleroderma	[210, 211]
	Thrombotic microangiopathy, malignant hypertension	[212, 213]
	Infarction	[84, 92]
	Interstitial nephritis, glomerular basement membrane glomerulonephritis	[215, 216]

CK concentrations of less than 1500 U/L (25 μ kat/L), a normal serum creatinine concentration, a normal WBC count, and no more than one additional risk factor for rhabdomyolysis (i.e., increased muscular activity, other mind-altering drugs, seizures) did not develop complications and had a shorter hospital stay [220].

In severe cases, laboratory values are consistent with values associated with profound rhabdomyolysis. Serum CK concentrations are reported in the range of 100,000 U/L (>1700 μ kat/L) [219]. Hyperkalemia, hyperphosphatemia, hyperuricemia, metabolic acidosis, and elevations of liver function tests may occur; disseminated intravascular coagulation may develop as a terminal event. In a study of 39 patients with rhabdomyolysis after cocaine use, seven developed disseminated intravascular coagulation, of which six died [98] (Table 4).

Uteroplacental Complications

The complications of cocaine use in pregnancy generally are thought to be secondary to its local vasoconstrictive effects on uterine blood flow [221, 222]. Maternal complications include spontaneous abortion, abruptio placentae, and premature labor [223, 224]. Fetal cocaine exposure results in developmental problems, including small head circumference, low birth weight, neurologic abnormalities, and uterogenital abnormalities [225–231]. The studies on the effects of cocaine on pregnancy and neonates are

controversial because their results are limited and include other confounding factors (study subjects may have less cocaine use, other substance abuse, poor maternal health and prenatal care), in some studies showing little or no effect [232, 233].

Diagnosis

The diagnosis of acute cocaine toxicity is based largely on the patient’s history and physical examination. Testing for cocaine’s metabolites rarely adds valuable information in an acute scenario but may have uses for epidemiology, child abuse and neglect, and evaluation of dual diagnosis in psychiatric patients. Although false-positive or false-negative results for cocaine metabolites in urine are rare [234–236], caution should be made when judging a clinical scenario based on a drug screen usually based on metabolites in urine which may be present for days and not testing for parent cocaine in blood [237]. Testing for parent cocaine in urine in a retrospective study among 61 patients did not identify a difference in vital signs, chief symptoms, nor treatment between patients with cocaine metabolites only versus parent cocaine as well as metabolites in urine [238]. Many patients present with symptoms of mild toxicity and physical examination findings consistent with a sympathomimetic toxic syndrome, which is clinically indistinguishable from other stimulant drug toxicity. Most important clues to deciphering the etiology of the agitated patient are found in the vital signs. Hypertension, tachycardia, and hyperthermia are customary. An elevated body temperature (41.1 °C [>106 °F]) of any etiology is more ominous, however, than an elevated pulse or blood pressure. This information should be obtained early in the management. Because the differential diagnosis for altered mental status with hyperthermia is extensive, other immediate causes, including hypoxia, hypoglycemia, and infection, should be considered and treated promptly.

Unless a patient presents with a severe complication from cocaine, most laboratory tests are not helpful. Electrolyte abnormalities and acid–base

abnormalities are generally secondary to seizures or agitation and hyperthermia and subsequent rhabdomyolysis. Those patients with altered mental status, hyperthermia, seizures, or hypotension or hypertension should be monitored for hypokalemia, hyperkalemia, and hypocalcemia because subsequent dysrhythmias may be a cause of mortality in patients with rhabdomyolysis. Elevated liver enzymes and coagulopathy are ominous findings in the severely hyperthermic patient [239].

Clinical status should guide the use of adjunct diagnostic tools. A chest radiograph is helpful in clarifying the existence of pulmonary pathology or large vessel injury. Extrapulmonary air in the thoracic cavity or a widened mediastinum may be visible.

Similarly, patients with chest pain should have an ECG and cardiac enzyme determination to help exclude cardiac ischemia and infarction. Although these parameters are not perfect tools in diagnosing cocaine-associated myocardial infarction, they are beneficial when definitively abnormal or evolving.

The ECG has a low predictive value for detection of an acute myocardial infarction in patients presenting with cocaine-related chest pain. The sensitivity of the ECG is only 36%, while the specificity is 90% [132].

Non-specific ECG abnormalities in patients with cocaine-associated chest pain are a common manifestation. ECGs of many patients with cocaine-induced myocardial infarctions are normal or nondiagnostic [90, 132, 135]. The typical ECG abnormalities include ST-segment elevations or depressions, T-wave inversions, QRS prolongation and Q waves, and J-point elevation due to early repolarization [132, 134, 135, 240, 241]. J-point elevation on the ECG of patients with cocaine-associated chest pain appeared with a mean frequency of 35%. These elevations in the precordial leads are misinterpreted easily as acute myocardial infarction. In one study, 43% of patients presenting with cocaine-associated chest pain had ST-segment elevations in the precordial leads, meeting ECG criteria for the use of thrombolytic therapy, with none of them meeting biochemical criteria for infarction [134]. The high

frequency of abnormal ECGs in this group of patients was attributed to early repolarization.

This subject is confounded further by the fact that similar ECG abnormalities are often found in asymptomatic chronic cocaine abusers [138, 242]. In cocaine-addicted patients admitted for inpatient detoxification who wore ambulatory ECG monitors, frequent ST-segment elevations were observed; 87% of the episodes for ST-segment elevations were silent. These ECG changes continued to occur in 25% of patients after 2 weeks of drug abstinence. None of the patients had ECG abnormalities after 6 weeks of drug abstinence [138].

In contrast, cardiac troponins are considered the most sensitive and specific biomarkers for diagnosing myocardial infarction in the setting of cocaine use. An early study addressing this issue in 19 consecutive cocaine-related chest pain patients showed that both troponin I and troponin T showed a specificity of 94% (one patient's sample was not adequate for testing), although 74% had elevated CK, 16% had an elevated CK-MB concentration, and only 16% had an ECG described as normal. None of the patients were diagnosed with myocardial infarction based on ECG or clinical criteria [243]. Similar specificities were found in a subsequent study that compared troponin I with CK-MB in patients undergoing serial marker analysis for exclusion of myocardial infarction after cocaine use [244]. Another retrospective study of 111 patients with cocaine-associated chest pain evaluated with CK and CK-MB as well as troponin T did not identify any patients with an elevated troponin T, and one with elevated CK-MB, although none of the patients suffered myocardial infarction in hospital or 30-days later [245]. The value of CK and CK-MB measurements in cocaine-associated chest pain to diagnose cocaine associate-myocardial infarction may be inadequate and confound the diagnosis. These laboratory values may be elevated in patients with cocaine-associated chest pain with subsequent negative troponin I levels [243]. A study among 97 patients with chest pain of which 19 had recently used cocaine, with a similar rate of myocardial infarction in patients with or without recent cocaine use

(12% versus 11%), found a nonsignificant difference in the specificities of CK-MB for myocardial infarction in patients with and without cocaine use (75% vs. 88%). In contrast, the specificities of troponin I were equal (94% vs. 94%) [246]. The timing of troponin testing relative to onset of chest pain after cocaine use and the presentation to the emergency department has not been well studied in the era of ultra sensitive troponin assays, though we believe that based on the experience in cocaine-associated chest pain with an abbreviated protocol with standard troponin assays [247], it would be reasonable to assume that the standard approach for evaluation of ACS in low-risk patients would also be applicable in these patients.

In patients with cocaine-associated chest pain, cardiac imaging studies may be useful in determining whether the chest pain is of cardiac origin. A prospective evaluation by myocardial perfusion imaging with ^{99m}Tc -sestamibi showed that only 5 of 216 (2%) patients presenting with cocaine-associated chest pain had a positive test, with two of five patients having enzymatic evidence for infarction [243]. Single-photon emission computed tomography myocardial perfusion imaging (SPECT MPI) was safely and adequately used as a triage tool in 151 patients presenting with myocardial ischemic symptoms secondary to cocaine use and 1213 patients without recent cocaine use. There was no difference in the distribution of SPECT MPI results in patients who presented with symptoms of ACS who used cocaine and those who did not (normal 72%, equivocal 23%, and abnormal 6%). In addition, there was no difference in the mean gated left ventricular ejection fraction in either population [248].

Cardiac catheterization may be able to localize an existing coronary lesion in cocaine-associated myocardial infarction. Of 52 patients with cocaine-associated myocardial infarction who underwent angiography, an initial report found that 67% had significant coronary disease [137]. This high incidence of disease is found mainly because of selection bias, with angiography being performed preferentially in patients who were considered high risk [90, 151]. In a more current study of 90 patients with

cocaine-associated chest pain who underwent angiography, 50% had no significant coronary artery stenosis. Single-, two-, and three-vessel coronary artery disease were present in 32%, 10%, and 5.6% of patients, respectively [249]. In 31 patients who tested positive for myocardial infarction by elevated troponins, coronary artery disease was found in 75%, compared to 35% of those (59 patients) without myocardial infarction [249].

In patients who arrive at the hospital with a cocaine-associated myocardial infarction, the incidence of complications ranges from 19.7% to 28% [90, 137]. These complications consist of congestive heart failure, nonsustained ventricular tachycardia, sustained ventricular tachycardia, supraventricular tachycardia, and bradydysrhythmias. In Weber and coworkers' study to validate a brief observation period for cocaine-associated chest pain, among those patients considered at high risk for ACS (ST-segment elevation or depression >1 mm, elevated troponin concentration, recurrent chest pain, or hemodynamic instability) and not included in the protocol, there was a 23.8% incidence of myocardial infarction (10/42) and a 23.8% incidence of unstable angina (10/42) [247]. Despite this high frequency of occurrence, the mortality during acute hospital stay in one study of 246 patients presenting with chest pain following cocaine use was 0% (95% confidence interval 0–2%) [137]. More importantly, patients who developed complications tended to do so within the first 12 h after emergency department arrival. More than half of the complications already have manifested by arrival [137]. More recent retrospective data from the Acute Coronary Treatment and Intervention Outcomes Network (ACTION) Registry of 102,028 patients with myocardial infarction and data collected regarding self-reported cocaine use in the previous 72 h or positive urine test for cocaine showed that the 924 patients with recent cocaine use and myocardial infarction were more likely to have ST-segment elevation myocardial infarction (STEMI) (46.3% vs. 39.7%) and to present with cardiogenic shock at arrival (13% vs. 4.4%), though they did not have an increased hospital mortality (adjusted odds ratio 1.00, 95%

confidence interval 0.69 to 1.44, p value = 0.98) as compared to patients with myocardial infarction not related to cocaine [250].

In the absence of the complications mentioned above, risk stratification of patients who present with cocaine-associated chest pain on the basis of established criteria for ACS (Thrombolysis for Myocardial Infarction scores, ECG changes and troponin concentrations) is safe and may prevent unwarranted hospital admissions. Studies demonstrate the safety of observation of low- to intermediate-risk patients for a 9–12 h period with ECG monitoring and serial troponin I evaluation. The admission rates of patients with high risk for ACS by the criteria defined above have been similar: 11.2–12% [247, 251]. A more recent study found that an abbreviated time of observation of 8 h was safe in this population [245]. On 30-day follow-up, one study reported one cardiac complication in a patient found to have underlying CAD with multiple cardiac risk factors. The second study reported no deaths and four (2%) nonfatal myocardial infarctions in patients who had continued to use cocaine [247, 251].

There is limited diagnostic utility in the use of provocative stress testing before discharge in patients that are less than 40 years of age with a nondiagnostic or normal ECG and normal cardiac markers who are evaluated for ACS [252, 253]. This seems to be the case as well for patients who use cocaine and present with similar symptoms since most of this population are also under 40 years of age and have low risks for ACS. Of 158 patients who underwent cardiac stress testing after presenting with cocaine-associated chest pain and an uneventful 9–12 h observation period, only four were positive. Subsequent cardiac angiography revealed that two of them had multivessel disease, one had nonocclusive disease, and one had no evidence of coronary artery disease [247]. Furthermore, positive stress testing may lead to unnecessary costly and potentially harmful interventions [254]. Stress testing in patients with cocaine-associated chest pain after a period of uneventful observation should not be routinely performed in the emergency department and may be considered, depending on cardiac risk factors and symptomatology.

Studies using coronary CT angiography to assess the extent of ACS are inconclusive. Patients with cocaine-associated chest pain with low to intermediate risk for ACS with normal troponin concentrations had no difference in calcium scores, extent of coronary artery stenosis, and extent of calcified and noncalcified plaques when compared with noncocaine users [160, 255, 256]. In contrast, similar studies found significantly higher coronary calcium scores [161], higher overall number of plaques, and more partially calcified plaques [257] in patients with cocaine use. Other forms of cardiac imaging to visualize injury such as cardiac magnetic resonance imaging (MRI) failed to find myocardial delayed enhancement which is indicative of myocardial fibrosis due to previous myocardial infarction in patients experiencing cocaine-associated chest pain with low to intermediate ACS risk [256].

The long-term outcome of patients who present to the emergency department with cocaine-associated chest pain also seems favorable. There is no difference in the 30-day outcomes among patients who undergo stress testing in the ED compared with those who do not [247]. These patients have a 1-year survival of 98% and an incidence of late myocardial infarction of only 1% [258].

Although the mortality from complications secondary to cocaine-induced myocardial infarction is low, certain patients need close monitoring. We recommend the following criteria for identifying patients who are at greatest risk:

- Complications such as hypotension, dysrhythmias, or congestive heart failure at presentation or during a 12-h observation period
- Persistent chest pain despite standard therapy
- An ECG with features of classic or evolving myocardial infarction
- A positive troponin

When available, helical chest CT or angiography may be performed if an aortic dissection or a pulmonary infarction is suspected. In a prospective multicenter study of 4356 patients for whom D-dimer was ordered to rule-out pulmonary

embolism of which 68 (2%) admitted to recent cocaine use, recent cocaine use was found to be independently predictive of a positive D-dimer (OR = 2.02; 95% CI 1.20–3.38) and significantly associated with false-positive D-dimer results (OR = 2.14; 95% CI 1.26–3.60) [259].

The etiology of global or focal neurologic findings may be elucidated by a head CT scan or magnetic resonance imaging/magnetic resonance angiography. The authors recommend that recent cocaine use should not influence the standard diagnostic approach to new-onset seizures and other etiologies should be excluded. Similarly, in patients presenting with complaints of headache in which a subarachnoid hemorrhage is in question, the standard diagnostic approach is a lumbar puncture if an initial head CT scan is normal.

Treatment

Recommendations for treatment of cocaine toxicity are based on a limited array of scarce high-quality evidence, case series, isolated cases, and expert evidence. A recent systematic literature review for the treatment of cocaine cardiovascular toxicity highlighted the fact that a meta-analysis of effect is not possible due to the limited number and quality of trials, significant diversity in protocols, and subject selection. The data available in this study was analyzed qualitatively, without measures of effect, and reflects conflicting results among practically all treatment modalities [260].

The peripheral complications of cocaine toxicity are likely the result of an increased central excitatory state secondary to an increased sympathetic outflow. Treatment is directed primarily at restoring this central imbalance, which by itself treats many of the peripheral manifestations providing specific treatment to the particular organ complications. Because the major cause of mortality from cocaine toxicity is secondary to the exceedingly severe psychomotor agitation and subsequent hyperthermia, primary attention is given to obtaining control of this agitated state (Grade II-3 recommendation).

Unless there is evidence of a catastrophic CNS or cardiovascular event, most patients with

cocaine toxicity present to the hospital verbal and fully active and without the need for emergent airway management with endotracheal intubation. In an agitated delirious patient, hypoxia and hypoglycemia (likely unrelated to cocaine) may be diagnosed immediately by obtaining bedside pulse oximetry and a rapid reagent glucose.

Hyperthermia should be recognized early and treated immediately due to significantly increased risk of mortality. Body temperatures greater than 41.1 °C (106 °F) place the patient at great risk for end-organ injury. Any temperature greater than 43.3 °C (110 °F) suggests a poor prognosis [239]. Management of hyperthermia consists of rapid immersion in an ice water bath while maintaining control of agitation (Grade II-2 recommendation) [261, 262]. Adequate sedation controls the motor activity and prevents further temperature elevation.

Indications for ICU Admission in Cocaine Poisoning

Chest pain with ischemic changes on ECG, evolving ECG, persistent chest pain despite therapy, myocardial infarction, thrombolysis, symptomatic dysrhythmias

Focal neurological signs, prolonged or focal seizures, coma, subarachnoid hemorrhage, intraparenchymal hemorrhage, delirium

Aortic dissection, rupture, uncontrolled hypertension, hypotension

Hemorrhage, embolism, hypoxia, pneumothorax, pneumomediastinum

Rhabdomyolysis with signs of acute kidney injury, renal infarction

Abruptio placentae, spontaneous abortion with prolonged bleeding

Mesenteric ischemia and infarction, splenic infarction, gastrointestinal perforation

Hyperthermia with altered mental status, metabolic acidosis

Evidence of disseminated intravascular coagulation (complication of hyperthermia)

Although agents such as haloperidol, chlorpromazine, pimozide, and propranolol may normalize some of the vital signs, they do not protect

against the centrally mediated motor activity and lethality in most experimental models [115, 263, 264]. When comparing different therapeutic strategies in cocaine-toxic dogs, survival correlated best with therapies that corrected body temperature [99]. Benzodiazepines decrease mortality by controlling the agitation and lowering the body temperature. Other strategies to control agitation, such as using ketamine [265] or newer antipsychotics, are less studied than benzodiazepines in cocaine-toxic individuals and there are concerns regarding risk of seizure, exacerbation of vital sign abnormalities (i.e., hyperthermia, hypertension, tachycardia) and QT prolongation not present with benzodiazepines [266–268].

Despite an elevated blood pressure, hyperthermic patients ordinarily are volume depleted secondary to the increased insensible fluid losses largely in sweat [269]. Hydration status, electrolytes, and substrates should be replenished. When restrained, the patient should not be covered completely without adequate heat dissipation. Although effective for malignant hyperthermia, dantrolene is not effective for cocaine toxicity [270–272].

Violent activity may be controlled with temporary physical restraint, if necessary, until sedation is achieved chemically. Physical restraint is not recommended in the absence of chemical sedation due to the increased risk of harm to both patient and providers. Continuous motor activity while in restraints may worsen hyperthermia from the increased muscle activity. Wrist and ankle bands instead of blankets should be used for physical restraints because blankets impair heat dissipation and worsen rhabdomyolysis and lactic acidosis.

Benzodiazepines are the pharmacologic agents of choice for sedation of cocaine-induced agitation (Grade II-2 recommendation). These agents control cocaine-induced agitation, hypertension, tachycardia, and hyperthermia in animal models [99, 273, 274]. Similarly, benzodiazepines resolve cardiac performance and symptoms of chest pain in patients with cocaine-associated coronary syndromes (Grade I recommendation) [275]. Additionally, they effectively treat agitation secondary to increased sympathomimetic activity from alcohol or sedative-hypnotic

withdrawal. Benzodiazepines are safe for controlling CNS agitation from other potential causes, such as an infection. We recommend incremental intravenous doses of 5–10 mg of diazepam (or equivalent doses of midazolam) be given to adults until the desired level of sedation is achieved. As the mental status becomes controllable with treatment, the peripheral manifestations of cocaine toxicity also are alleviated (hypertension, tachycardia, hyperthermia, diaphoresis).

An elevated blood pressure that fails to respond to sedation may be controlled with nitroglycerin (starting dose 10 µg/min) or phentolamine (5–20 mg) with titration to a normal blood pressure. These drugs may be given without risk of cerebral hypoperfusion in patients without long-standing hypertension. Cocaine's pharmacokinetics should be kept in mind when using hypotensive drugs as its toxic effects wear off.

Additionally, benzodiazepines control seizures that may occur early at presentation from acute cocaine intoxication or afterward as a manifestation of a CNS or cardiovascular complication. In a canine model of cocaine toxicity, only diazepam and induced hypothermia were able to reduce the incidence of seizures, control tachycardia and hypertension, and improve outcome [99]. Ultimately, barbiturates or propofol may be effective in terminating seizure activity. Because of cardiovascular and respiratory depression caused by these agents, cardiac monitoring and ventilatory support must be provided [276].

If a neuromuscular blocker is used, electroencephalogram monitoring is necessary because central seizure activity may otherwise be overlooked. A nondepolarizing neuromuscular blocker is preferable because of the potential of a depolarizing agent to exacerbate hyperkalemia and rhabdomyolysis. Succinylcholine is also degraded rapidly by plasma cholinesterase, the same enzyme that metabolizes cocaine. Theoretically, use of these agents simultaneously may extend the clinical effects of either or both.

Because most exposures to cocaine are from nasal insufflation or from inhalation, gastrointestinal decontamination generally is not an issue. Ingestion may be lethal because this type of exposure occurs in the setting of smuggling large

amounts of cocaine. Decontamination may require the administration of activated charcoal and, if packets were ingested, whole-bowel irrigation. Any symptomatic patient in whom there is confirmed packet ingestion should undergo a laparotomy to remove the cocaine packets (Grade III recommendations). Internal concealment of drug in patients with suspected cocaine toxicity that is refractory to treatment or with clinical effects lasting longer than expected should be considered, among other differential diagnoses.

Treatment of the cardiac manifestations of cocaine toxicity is directed at reversing the pharmacological effects that cause ischemia or dysrhythmias. As stated earlier, benzodiazepines assist in normalizing blood pressure and heart rate and diminish myocardial oxygen demand. If the physical examination denotes catecholamine excess, benzodiazepines should be the initial treatment modality in patients with cocaine-associated chest pain [277] (Grade I recommendation). Theoretically, aspirin may prevent cocaine's thrombogenic effects. Aspirin has an extensive beneficial record in the treatment of patients with ischemic heart disease. We recommend that 325 mg of aspirin be administered in patients with cocaine-associated ischemic symptoms unless there is also a suspicion of cerebral hemorrhage (Grade III recommendation).

Clinical and angiographic data support the use of nitroglycerin to relieve cocaine-associated chest pain caused by coronary artery vasoconstriction [278, 279]. Cocaine-induced vasoconstriction was abolished in nine patients given sublingual nitroglycerin in a dose sufficient to reduce mean arterial pressure by 10–15% [278]. As in patients with classic ischemic chest pain, nitroglycerin should be the principal treatment for patients with cocaine-associated chest pain as well.

Because cocaine's vasoconstrictive effects are mediated by an α -adrenergic mechanism, the use of β -adrenergic antagonists for the treatment of cocaine-associated cardiac toxicity has resulted in deleterious consequences in human and animal studies [66, 99, 148, 197, 274, 280, 281]. In volunteers given 2 mg/kg of cocaine intranasally or intravenously, the administration of the

β -adrenergic antagonist propranolol caused further coronary artery constriction visualized angiographically [148–150, 278]. Similarly, a prospective cohort using esmolol to treat cocaine toxicity in seven patients resulted in three adverse effects including one hypotensive patient and one requiring intubation [281]. The use of mixed β -adrenergic antagonists, including labetalol, is contraindicated in patients with acute toxicity [280]. Despite this evidence of harmful and potentially lethal effects [282] of β -adrenergic antagonist use in the acutely cocaine-toxic patient presenting with chest pain, there is a resurgence of studies that create controversy regarding their use in this population, as well as the results of a systematic review of the literature [260]. However, these studies have several common limitations that have not changed the authors' conviction of β -adrenergic antagonist use contraindication in acute cocaine toxicity that is manifested by the sympathomimetic toxic syndrome (Grade II-3 recommendation). In all of these studies, data was gathered retrospectively by chart review, cocaine use was determined by urine test rather than by recent cocaine history, the timing and route of β -adrenergic antagonist administration was not exactly determined, administration of β -adrenergic antagonist was at the discretion of the clinician, and the populations in which the β -adrenergic antagonists were administered had more ACS risk factors [283–285]. In weighing the evidence of the risk/benefit of their use in patients with cocaine use and chest pain, the American Heart Association cautions against their routine use [286, 287].

Phentolamine, an α -adrenergic antagonist, reverses cocaine-induced ischemia [150, 288]. Based on limited evidence, we recommend a low starting dose (1 mg) of phentolamine to avoid hypotensive effects, while maintaining anti-ischemic effects (Grade I recommendation) [17]. This dose may be repeated in 5 min and be titrated to control of symptoms and blood pressure. This vasodilating agent with rapid-onset and short-lived pharmacodynamics is preferred because of its simple, dependable control.

Large multicenter clinical trials found calcium channel antagonists not beneficial in the treatment

of myocardial ischemia unrelated to cocaine, whereas in cocaine toxicity, smaller animal and human studies yielded conflicting results [150, 289–297]. In some animal studies, calcium channel antagonists decreased the incidence of seizures and cardiac dysrhythmias and increased survival [150, 289, 290, 295, 297]; others reported opposite results [291–293]. Verapamil reversed cocaine-induced coronary artery vasoconstriction in a human model [296] and is recommended by some authors for the treatment of refractory ischemia [17]. Because of these equivocal results, we recommend that calcium channel antagonists should be used with caution and only when other therapies have failed (Grade III recommendation).

Angiography and angioplasty are advocated by current guidelines in patients with cocaine-associated STEMI [286]. Angiography has been performed safely and successfully in patients with cocaine-associated chest pain [244, 298]. The poor predictive value of the ECG in cocaine-induced acute myocardial infarction and the low incidence of complications after such an event and the potential life-threatening adverse effect of thrombolytic therapy should discourage the routine use of thrombolytic therapy in this setting. In addition, because many patients with cocaine-induced myocardial infarction do not have a thrombus, cardiac catheterization may provide a definitive diagnosis and the ultimate reperfusion strategy when available. If invasive reperfusion facilities are unavailable, and the patient has clear ECG evidence of myocardial infarction without contraindications, thrombolytics may be used. Although the clinical safety of the use of thrombolytic therapy for cocaine-associated myocardial infarction has been documented [250, 299], this treatment modality has significant potential complications [300, 301] and remains a second-line therapy (Grade II-3 recommendation).

Most benign dysrhythmias secondary to cocaine toxicity respond to sedation, fluid administration, and cooling. Supraventricular dysrhythmias and atrial fibrillation that do not respond to this initial treatment may be treated with diltiazem or verapamil. Wide-complex supraventricular tachycardia occurring in an acutely cocaine-intoxicated patient is most likely secondary to cocaine's sodium channel-blocking effects on

the conduction system of the heart. As such, this effect is similar to that of class I antidysrhythmic drugs [168]. Animal and human data report the reversal of the subsequent QRS prolonging effect on the ECG with treatment with hypertonic sodium bicarbonate [59, 302–304]. We recommend a bolus of 1–2 mEq/kg of hypertonic sodium bicarbonate in patients with QRS widening in a pattern characteristic of sodium channel blockade (Grade III recommendation).

Ventricular tachycardia may be treated with lidocaine (Grade III recommendation). The effects of lidocaine on cocaine-poisoned animals are contradictory [304–306]. Concern of administering another class I antidysrhythmic agent with definitive CNS toxicity in cocaine toxicity exists. Evaluation of patients having cocaine-induced myocardial infarction who received lidocaine for various indications showed, however, clear absence of fatality, seizures, or cardiac complications in the emergency department or during subsequent hospitalization [169]. Amiodarone is commonly recommended for management of wide-complex tachycardias. However, the safety and efficacy of amiodarone in cocaine-toxic individuals is unstudied and its use cannot be recommended.

A small number of patients present with manifestations of toxicity that include myocardial dysfunction, wide-complex tachycardia and cardiocirculatory collapse refractory to volume repletion, sodium bicarbonate, and lidocaine. These patients require vasoactive support, preferably with a direct acting pressor, i.e., norepinephrine. Furthermore, in these patients, there may be a role for lipid emulsion therapy. There are limited specific experiences with its use in severe cocaine toxicity [307, 308], although there is more extensive experimental use in local anesthetic toxicity and with other drugs [309]. At this stage we believe that it should be considered a rescue therapy due to the lack of experience and concerns about its safety [310].

Besides the same recommendations concerning supportive care, control of psychomotor agitation, and treatment of hypertension in acute cocaine toxicity described above, there is no reason that further treatment of patients suffering a

stroke after the use of cocaine should not follow similar guidelines as those for individuals not exposed to cocaine. Retrospective data have shown that for subarachnoidal hemorrhage, cocaine use was associated with poor prognosis but not with vasospasm requiring treatment with angioplasty [123]. A small retrospective study showed no differences in safety or outcome with acute ischemic stroke treated with thrombolytic therapy in cocaine-positive and cocaine-negative patients [311].

Gamma-hydroxybutyrate (GHB) is structurally related to the neurotransmitter gamma-aminobutyric acid (GABA) and is present endogenously in the human brain as a metabolite of GABA in low concentrations. GHB has had a variety of different medicinal uses since it was first introduced as a general anesthetic in 1964 [1]. Although it is not routinely used for this purpose, it is still sometimes used in the management of alcohol withdrawal and the treatment of narcolepsy with cataplexy [2, 3]. In recent decades there has been increasing recreational use of GHB amongst clubbers for its stimulant and prosexual effects, particularly amongst the men who have sex with men community [1, 4–6]. The related precursors and analogues, gamma-butyrolactone (GBL) and 1,4-butanediol (1,4-BD), are not found endogenously. However, when they are used, they are metabolically converted to GHB resulting in clinical effects almost identical to GHB. The legal status of these compounds varies around the world, with control of GHB being more widespread. The widespread industrial use of GBL and 1,4-BD (e.g., in cleaning products) results in them often being less subject to legal controls than GHB [4]. This chapter will cover the pharmacology of these compounds, and patterns of acute toxicity, and associated chronic dependence.

Biochemistry and Clinical Pharmacology

Gamma-hydroxybutyrate has the empirical formula $C_4H_8O_3$ (Fig. 1) and molar mass of 104.10 g/mol. It is often seen as the sodium salt (molar mass, 126.06 g/mol). Its melting point is $-17\text{ }^{\circ}\text{C}$ and boiling point is $178\text{--}180\text{ }^{\circ}\text{C}$. GHB, unlike its analogues, has previously had medical uses. Historically, it was used as a general anesthetic, antidepressant, and in the management of alcohol withdrawal (particularly in Italy) [3]; it is not currently used as an anesthetic or antidepressant. GHB is clinically used in the treatment of narcolepsy with cataplexy, marketed under the trade name, (Xyrem) [2, 7, 8]. Fermentation can result in production of small amounts of GHB, and it can be detected at low concentrations in alcoholic and nonalcoholic drinks and other food substances fermented particularly from grapes (typical reported concentrations are up to 10 mg/L) [9]. Data from animal and human studies showed GHB administration resulted in growth hormone secretion. In the 1970s and 1980s, it was used in the bodybuilding community as it was thought to increase muscle mass, although the actual evidence that it increased lean muscle mass is weak [10–12].

Gamma-butyrolactone has the empirical formula $C_4H_6O_2$ (Fig. 2) and molar mass of 86.09 g/mol. Its melting point is $43.5\text{ }^{\circ}\text{C}$ and boiling point is $204\text{ }^{\circ}\text{C}$. GBL is synthesized industrially through dehydrogenation of 1,4-butanediol; it can also be synthesized by oxidation of tetrahydrofuran. There are no medicinal uses for GBL. However, it has many uses as an industrial solvent and chemical reagent. It is also used as solvent in domestic products such as nail polish and superglue removers and household

cleaning products such as floor strippers. As a result of fermentation, GBL, like GHB, has also been detected in wine and other food substances fermented from grapes (concentrations not reported); there is the potential that this detection is related to the acidic nature of certain beverages favoring a shift in the equilibrium of GHB/GBL towards GBL [9]. Since GBL is a lactone (i.e., a cyclic ester), alkaline conditions result in ester saponification which converts GBL into GHB. The equilibrium for the interconversion of GHB and GBL depends on the pH of the environment.

1,4-butanediol has the empirical formula $C_4H_{10}O_2$ (Fig. 3) and molar mass of 90.12 g/mol. Its melting point is $20.1\text{ }^{\circ}\text{C}$ and boiling point is $235\text{ }^{\circ}\text{C}$. There are several methods of synthesis of 1,4-BD, including (i) reaction of acetylene with formaldehyde to form 1,4-butyndiol, which is hydrogenated to form 1,4-BD; (ii) conversion of propylene oxide to allyl alcohol, which is hydroformylated to form 4-hydroxybutyraldehyde, which is hydrogenated to form 1,4-BD; and (iii) conversion of maleic anhydride to the methyl maleate ester which is then hydrogenated. Biological synthesis pathways using genetically modified organisms have also been reported [13]. There are no medicinal uses for 1,4-BD, but it is used widely in industry as a solvent, in the manufacture of plastics and related products and in the synthesis of GBL.

Pharmacokinetics and Pharmacodynamics

Gamma-hydroxybutyrate and its analogues are rapidly absorbed following oral administration. Although GHB is available as a powder and could be administered by nasal insufflation, there are no reports on the absorption kinetics of this route. In addition, there are no data on the pharmacokinetics following intravenous injection of GHB or GHB analogues.

Eight healthy volunteers received an oral dose of 25 mg/kg GHB resulting in mean \pm standard

Fig. 1 Chemical structure of gamma-hydroxybutyrate (GHB)

Fig. 2 Chemical structure of gamma-butyrolactone (GBL)

Fig. 3 Chemical structure of 1,4-butanediol (1,4-BD)

error of the mean (SEM) time to peak concentration (T_{max}) of 41.3 ± 2.5 min with peak plasma GHB concentrations of 39.4 ± 25.2 $\mu\text{g/mL}$ [14]. The overall mean (SEM) volume of distribution for GHB in this study was 52.7 ± 15.0 L. In a study of alcohol-dependent patients using GHB, the median T_{max} (30 min) and mean maximum concentration (C_{max}) (54 ± 19 $\mu\text{g/mL}$) were similar following a 25 mg/kg dose to those reported in healthy volunteers. Additionally, repeated dosing every 12 h resulted in no change in median T_{max} (30 min) and mean C_{max} (55 ± 19 $\mu\text{g/mL}$) after 13 doses [15]. In a further study of 32 healthy volunteers, following the oral administration of 20 mg/kg (16 subjects) and 35 mg/kg (16 subjects) GHB, there was no difference in the median time to peak plasma GHB concentration (T_{max}) [20 mg/kg – 35 (range 35–60) minutes and 35 mg/kg – 35 (35–60) minutes] [16]. It should be noted in this study that the first blood samples were collected 35 min postadministration, and it is possible that both the T_{max} and C_{max} may have occurred prior to the first measurement.

In a study of eight human volunteers, the mean \pm standard deviation (SD) time to peak 1,4-BD concentration following a single oral dose of 25 mg/kg 1,4-BD was 26.3 ± 12.0 min with a mean maximum plasma concentration of 3.84 ± 4.57 mg/L [17]. The overall mean (SD) apparent volume of distribution for 1,4-BD was 19.7 ± 18.6 L. Animal studies suggest that GBL is more rapidly and completely absorbed, with a higher maximum concentration and shorter time to maximum concentration than GHB with equimolar doses [18–21]. There are no pharmacokinetic data demonstrating whether this is also the case in humans. However, one study reported more rapid onset of sleep with oral GBL in children than with GHB [22]. Gamma-hydroxybutyrate readily crosses the blood brain barrier [23, 24]. The transfer of GHB into the central nervous system (CNS) is mediated by monocarboxylate transporters (MCTs). A rat model using in vivo microdialysis demonstrated that brain extracellular fluid (ECF) concentration-time profiles closely follow the concentration-time profiles seen in plasma. Following

intravenous administration of GHB, T_{max} for plasma and ECF were 5 and 50 min, respectively, irrespective of dose administered (400 mg/kg, 600 mg/kg, and 800 mg/kg) suggesting no saturation of MCT transport of GHB across the blood–brain barrier across this range of concentrations. It should be noted that these doses are significantly higher than those reported to be associated with coma in humans (>50 mg/kg), and therefore it is unlikely that saturation of blood–brain barrier transfer by MCTs is likely to occur in humans [25].

Following absorption, both GBL and 1,4-BD are metabolized in vivo to GHB; GBL is rapidly metabolized by calcium-dependent serum lactonases, whereas 1,4-BD is metabolized in the liver through two step conversion via hepatic alcohol dehydrogenase to gamma-hydroxybutyraldehyde followed by metabolism onto GHB via hepatic acetaldehyde dehydrogenase [21, 26–29]. This metabolism is rapid following absorption, with GHB being detected in volunteers within 5 min of 1,4-BD ingestion. Those without detectable GHB also had undetectable 1,4-BD concentrations probably reflecting delayed absorption rather than delayed metabolism of 1,4-BD to GHB [17]. In vivo animal studies in rats have shown that both ethanol and fomepizole competitively block the metabolism of 1,4-BD to GHB, through preferential metabolism by (ethanol) or direct inhibition of (fomepizole) alcohol dehydrogenase [29–31]. This is not used routinely in clinical practice to treat acute 1,4-BD toxicity since by the time acute toxicity occurs, a significant proportion, if not all, of the 1,4-BD will have been metabolized into GHB. However, there is the potential that co-use of ethanol with 1,4-BD may delay its metabolism because ethanol is preferentially metabolized and acute toxicity may therefore be delayed.

Following administration of 25 mg/kg of 1,4-BD to volunteers the elimination half-life (t_{1/2}) for 1,4-BD was 39.3 ± 11.0 min and the time to maximal GHB concentration was 39.4 ± 11.2 min after 1,4-BD administration with undetectable 1,4-BD concentrations by 4 h of dosing [17]. This human volunteer study also identified significant inter-individual variation in

the metabolism of 1,4-BD to GHB. Half the volunteers had rapid and extensive conversion of 1,4-BD to GHB and the other half had slower clearance of 1,4-BD, which the authors related to ADH-IB G143A polymorphism and resultant differences in activity of alcohol dehydrogenase. However, it should be noted that text in the paper conflicts with the information in the tables, and it is not clear how the authors defined which subjects were fast or slow metabolizers.

Gamma-hydroxybutyrate is rapidly metabolized via succinic acid semialdehyde to succinic acid, and studies suggest an elimination half-life of between 30 and 50 min [14–16, 27, 32]. The succinic acid produced is subsequently metabolized via the tricarboxylic acid cycle (the “Krebs cycle”). The mean residence time of GHB following oral ingestion (25 mg/kg) is reported to be around 58–73 min in both healthy volunteers and alcohol-dependent patients [14, 15]. This may suggest why users typically redose every 30–60 min when using GHB, due to the short mean residence time of GHB. In addition to the rapidity of GHB metabolism, this metabolism is also very extensive, with minimal amounts excreted unchanged renally. Following an oral dose of 25 mg/kg in both healthy volunteers and alcohol-dependent patients, the recovery of unmetabolized GHB in urine over the subsequent 24 h is only around 0.73–1.2% of the administered dose [14, 15]. Additionally, in a study of eight healthy volunteers given 25 mg/kg GHB, no GHB was detected in any of the samples collected at 24 h postingestion. Of those collected 12 h postingestion, four had GHB detected but all at concentrations below the recommended 10 µg/ml threshold used to differentiate endogenous and exogenous GHB. Therefore, in forensic testing, all of the 12-h samples would have been reported as negative. There was no effect on urinary GHB concentrations in 16 healthy volunteers given 50 mg/kg GHB alone or in combination with 0.6 g/kg ethanol [32, 33]. Similar to other studies, GHB was only detected in samples collection between 0–3 and 3–6 h, although two subjects had urine GHB concentrations below the proposed 10 µg/mL threshold at 3–6 h postingestion. Although there appeared to higher early urine

GHB concentrations following lone administration (in samples collected between 0 and 3 h postadministration), when urine concentrations were standardized to creatinine there was no difference (898 µg GHB/mg creatinine for lone GHB administration compared to 980 µg GHB/mg creatinine for combined GHB/ethanol administration). Interestingly, there appeared to be a racial difference with lower urinary GHB concentrations in Caucasian subjects (7 subjects) compared to non-Caucasian subjects (9 subjects), although it should be noted that the numbers of subjects in each group are low. Following the oral administration of 20 mg/kg and 35 mg/kg GHB to 32 subjects, there was no difference in half-life of GHB of 36 ± 9 and 39 ± 7 min, respectively. However, when the area under the curve (AUC_{0–∞}) for the 35 mg/kg dose was normalized to 20 mg/kg, the geometric mean was significantly greater than that seen for the actual 20 mg/kg dose (20 mg/kg dose 15,747 nmol.min/mL; normalized 35 mg/kg dose 22,922 nmol.min/mL, $p < 0.01$), which suggests a nonlinear dose–response relationship for GHB despite no difference noted in the C_{max} or t_{1/2} between the two doses. GHB is actively reabsorbed from the proximal convoluted tubule of the nephron by both pH-dependent and sodium-dependent monocarboxylate transporters (MCT and SMCT) [34, 35]. There is the potential that inhibition of this reabsorption could increase renal clearance of GHB, therefore reducing its half-life increasing the overall renal elimination of unmetabolized GHB. Animal models in vitro and in vivo have shown that L-Lactate, which is transported by MCTs, can significantly reduce resorption of GHB and increase the renal clearance of GHB [34–38]. When L-lactate (330 mg/kg bolus then 121 mg/kg/h) was administered to rats 5 min after 60 mg/kg intravenous GHB, there was a significant reduction in the AUC and increase in renal clearance of GHB compared to when GHB was administered alone [AUC 131 ± 8.8 -vs- 74.4 ± 9.4 mg.min/mL, $p < 0.05$; renal clearance 0.415 ± 0.06 -vs- 0.910 ± 0.10 mL/min, $p < 0.05$], which resulted in a significantly reduced sleep time [GHB alone 126 ± 15.1 min compared to 87.0 ± 11.1 min, $p < 0.05$] [36]. It should be noted that MCTs are widely distributed

throughout the body, including at the blood–brain barrier [39]; there is the possibility that some of the reduction in sleep time seen was due to reduced CNS transfer of GHB rather than increased renal clearance of GHB. However, there is the potential for future studies to look at development of more specific renal MCT and or SMCT blockers to increase renal clearance of GHB as potential therapeutic agents to shorten the duration of coma in patients with acute GHB toxicity.

Gamma-aminobutyric acid is converted to succinic semialdehyde which can be converted to GHB. This conversion can be reversed to GABA by GHB dehydrogenase [23]. Gamma-hydroxybutyrate has a number of actions within the brain on different neurotransmitters, receptors, and pathways. Unlike other sedatives (e.g., benzodiazepines and barbiturates), GHB has no action on GABA-A receptors [40]. These actions include: (i) partial agonist actions at the GABA-B receptor (in part due to GHB itself and in part due to conversion to GABA); (ii) “GABA-like” activation of chloride channels; (iii) inhibition of pre-synaptic voltage-gated calcium channels (reduced neurotransmitter release); and (iv) increased opening of inward rectifying potassium channels (reduced postsynaptic excitability). These actions result in inhibition of dopamine release and glutamatergic transmission and increases in serotonin [24, 41, 42].

Chronic administration of GHB leads to cross-tolerance to baclofen (GABA-B receptor activity) but not flunitrazepam (GABA-A receptor activity) [43]. Gamma-hydroxybutyrate acts at GABA-B receptors to inhibit dopamine release, which can lead to upregulation of dopamine receptors with chronic use [44]. Animal studies show that GHB enhances dopamine concentration in the substantia nigra and the mesolimbic system both by reducing nerve firing and stimulating intracellular production [45]. During withdrawal, augmented dopamine release within these areas contributes to the psychotic symptoms seen. Chronic use of GHB (similar to that seen with chronic use of alcohol, benzodiazepines, and baclofen) is associated with down-regulation of the inhibitory GABA receptor [46–50]. This leads to

an increase in release of excitatory neurotransmitters and release of inhibition of excitatory pathways, such as dopaminergic neurotransmission pathways.

In an in vivo rat microdialysis model studying GHB concentrations in brain extracellular fluid, sleep time increased with increasing concentrations of GHB administered ($200\text{ mg/kg} - 90.4 \pm 14\text{ min}$ compared to $800\text{ mg/kg} - 171 \pm 12\text{ min}$) [25]. In a further rat model, increasing doses of GHB (200 mg/kg , 600 mg/kg , and $1,500\text{ mg/kg}$) were shown to have a dose-dependent effect on reducing respiratory rate with a matched increase in tidal volumes; this effect on both respiratory rate and tidal volumes was more prolonged in duration with higher doses of GHB administered [38]. In this model, administration of a GABA-B inhibitor (SCH50911) blocked the GHB mediated effects on respiratory rate and tidal volume, whereas the GABA-A inhibitor bicuculline had no effect. The effects of the GABA-B inhibitor were also dose-dependent, with a “threshold” to improve all respiratory pharmacodynamics parameters of 10 mg/kg . Administration of L-Lactate as an MCT inhibitor demonstrated that L-Lactate on its own had no effect on respiratory rate or tidal volume, but in the presence of GHB ($1,500\text{ mg/kg}$) L-lactate partially reversed some of the respiratory effects seen with GHB. Additionally, there was an additive effect when combined with SCH50911 (5 mg/kg), with improvement in all respiratory pharmacodynamics parameters. As previously described, the administration of L-Lactate was associated with an increased renal clearance. Therefore, it is likely that the respiratory effects of GHB are mediated through the GABA-B receptor and that the effect of L-Lactate is through increased renal clearance and associated reduced serum GHB concentrations rather than any effect directly on respiratory pharmacodynamics.

Doses in humans of 10 mg/kg , $20\text{--}30\text{ mg/kg}$, and $>50\text{ mg/kg}$ are reported to be associated with anxiolytic, hypnotic, and potentially acute severe unwanted effects such as coma, respectively. In context, many recreational users report using “a capful,” and the dose per cap varies between 500 mg to 5 g . In a human volunteer study of

32 healthy males given either 25 mg/kg or 35 mg/kg oral GHB, there was no significant effect of either dose of GHB on blood pressure (systolic or diastolic) or heart rate, although there was no report of the effect on respiratory rate or effort [16]. Volunteers reported that GHB was associated with sedation, stimulation, and dizziness lasting 2 h and that the sedation and dizziness was greater with the higher dose (no effect on stimulant effects was seen with increased dose). There was no reported acute pharmacological tolerance to GHB seen in this study, and higher plasma concentrations generally appeared to be associated with greater subjective effects. Interestingly, maximal sedative effects were seen with peak plasma concentrations (between 35 and 60 min after administration), whereas maximal stimulation and dizziness was seen around 60 min after administration (a time when GHB concentrations were already falling).

In a study of 1,4-BD in eight healthy volunteers, blood pressure transiently increased 15 min following administration, whereas oxygen saturations (respiratory rate and tidal volume values were not reported) decreased compared to placebo by 45 min following administration and remained reduced for around 100 min [17]. In terms of subjective effects, subjects were less awake/alert ($p = 0.013$), less able to concentrate ($p = 0.045$), and more light-headed/dizzy ($p = 0.01$) compared to placebo. Effects were maximal within 60–90 min postdosing and last for up to 4 h.

Prevalence of Use

Data on the prevalence of use of GHB and its related analogues GBL and 1,4-BD are not routinely collected at a population level. The United Nations Office on Drug and Crime 2015 World Drug Report did not report on the prevalence of use of GHB [51]. The 2015 European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) European Drug Report noted that only Norway provided information on the prevalence of use of GHB, with a last year prevalence of use rate in 15–64-year-olds of 0.1% [52]. The British Crime Survey has included GHB in its annual survey of 16–59-year-olds in England

and Wales since the 2009 survey (this has subsequently been renamed the Crime Survey England and Wales). The most recent data on the use of GHB and GBL was from 2011/2012, where 0.1% of those aged 16–59 years self-reported GBL/GHB use in the last year (an increase from 0.0% in the 2010/2011 survey). Although not reported in the 2011/2012 survey, in the 2010/2011 survey there was greater use in younger people (last year use 0.1% in those aged 16–24 years old compared to 0.0% in those aged 24–59 years old) [53, 54].

Since there is limited data available at a population level, most of the information on the prevalence of use of GHB and its related analogues comes from subpopulation level surveys, particularly school children and those who frequent nightclubs and other night-time economy venues. One of the difficulties in interpreting the prevalence of use of GHB and its related analogues relates to how survey participants have been asked about their use; in some they are asked about GHB, some ask about GHB and GBL separately and some combined GHB/GBL use. Therefore, it is not possible to easily determine the relative use of GHB compared to GBL. It should be noted that the majority of surveys do not ask about the use of the related analogue, 1,4-butanediol, and therefore there is little information available on its prevalence of use.

The European School Survey Project on Alcohol and other Drugs (ESPAD) is a longitudinal study surveying school students aged 15–16 years old every 4 years since 1995 to monitor trends in alcohol, smoking, and recreational drug use [55]. Approximately 103,000 European students were surveyed across 36 countries in the 2011 ESPAD survey [56]. Overall lifetime prevalence of use of any illicit drug was 18%, with a higher lifetime prevalence in boys (21%) compared to girls (15%); this was an increase from a lifetime prevalence rate of illicit drug use of 11% in the initial 1995 survey [56, 57]. In 2011, cannabis was the most prevalent illicit drug, with lifetime prevalence rates of 19% for boys and 14% for girls. In comparison, the average lifetime prevalence of use of GHB in the 2011 ESPAD survey was 1% and ranged from 0% to 3% across the 36 countries

involved. Although there was no overall difference in lifetime prevalence of GHB use between boys and girls, where there were gender differences in individual countries and typically rates amongst boys were higher than girls apart from Denmark (boys 0%, girls 1%) and Liechtenstein (boys 1%, girls 3%) where there was a reported higher lifetime prevalence in girls.

The Monitoring the Future project based in the USA surveys approximately 50,000 8th (13–14 year olds), 10th (15–16 year olds), and 12th (17–18 year olds) grade students every year, since the first survey of 12th graders was undertaken in 1975 [58]. While this longitudinal study includes questions on other recreational drugs, it does not include questions about the use of GHB or related analogues.

The Independent Drug Monitoring Unit in the UK, which conducts on-line surveys of drug users reported the relevance of GHB use between 1999 and 2002; although this data is rather historical now, there was a year-on-year increase in the reported lifetime prevalence of use of GHB from 2.8% in 1999 to 3.9% in 2002 [59].

The MixMag drug surveys undertook annual surveys of clubbers, initially through the MixMag dance magazine, and then more latterly through the MixMag Internet site. The initial surveys of 3,873 clubbers between 1999 and 2003 demonstrated lifetime use prevalence rates of GHB varying from 12.8% in 1999 to 17.5% in 2003, and last month use rates varying from 3.4% in 1999 to 3.1% in 2003 [60, 61]. These surveys did not include data on use of the related analogue GBL. The last MixMag drug survey, undertaken in 2010/2011, reported on the use of both GHB and GBL; lifetime prevalence of use of GHB amongst those surveyed was 14.8% and of GBL was 5.6%; last month use of GHB and GBL were 2.5% and 2.4%, respectively [62]. Since then, the MixMag Drug Survey has been expanded to become the Global Drug Survey, which includes different methods of recruitment for participants and also recruits from an increasing number of countries around the world. The 2012/13, 2013/14, and 2014/15 Global Drugs Surveys have not specifically included GHB or GBL in their annual reports; therefore, the latest data is available from

2011/12 only [63]. Since this change in the survey methodology, in the 2011/12 survey there appeared to be an increase in the prevalence of use of GBL compared to GHB in UK respondents (lifetime use 7.7% compared to 3.8%; last year use 1.6% compared to 1.5%). Similar to other studies, there appeared to be higher rates of use amongst those who self-classified themselves as “frequent clubbers,” with last year rates of use of 2.5% for GBL and 2% for GHB. In addition, this survey also specifically reported last year use amongst US respondents, although prevalence of use appeared to be lower than in the UK (US respondents: GBL 1% and GHB <0.5%).

There have been a number of in situ surveys undertaken amongst clubbers in a variety of different settings, which suggest a high prevalence of use of GHB and GBL amongst the “gay” (men who have sex with men) clubbing scene. In a survey of 408 individuals in bars in Amsterdam, the Netherlands, overall lifetime prevalence of GHB/GBL use was 10%, although there was a higher prevalence of use in those surveyed in “gay” (men who have sex with men) bars (17.5%) compared to those surveyed in “more mainstream” bars (<5%) [6]. A survey of 308 clubbers in “gay friendly” dance clubs in South East London in 2010 reported a higher lifetime prevalence of use of GHB in comparison to GBL, although more recent use of GBL was higher than GHB: (i) lifetime GHB 34%, GBL 27%; (ii) last year GHB 22%, GBL 24%; (iii) last month GHB 14%, GBL 19%; (iv) already used/planning use on the night of the survey GHB 7%, GBL 14% [64]. In a subsequent in situ survey of 315 clubbers in the same South East London nightclubs 1 year later in the summer of 2011, use of either GHB and/or GBL on the night of the survey was the second most common drug (24% of participants) after mephedrone (41% of participants) [5]. GHB/GBL was also the second most favorite drug (12% of participants) in this survey, again behind mephedrone (20% of participants).

There is a similar pattern of higher reported use of GHB and GBL amongst men who have sex with men attending sexual health clinics [65]. In a

self-completed questionnaire survey of 729 males attending two London sexual health clinics, there was a significantly greater use of both GHB and GBL amongst the 254 men who have sex with men (MSM) survey participants compared to the 475 non-MSM participants: (i) lifetime GHB use 22.7% compared to 5.7%; (ii) last month GHB use 2.4% compared to 0.2%; (iii) lifetime GBL use 16.1% compared to 2.7%; and last month GBL use 3.1% compared to 0.2%. Interestingly, similar to the in situ nightclub surveys, although lifetime use of GHB was greater than GBL, more recent use demonstrated a potential switch towards GBL use.

Clinical Presentations and Life Threatening Complications

Acute Toxicity

In addition to the discussion of acute toxicity related to the use of GHB below, there is the potential for elevated GHB concentrations as a result of a rare autosomal recessive condition known as succinic semialdehyde dehydrogenase deficiency which was first described in 1981. This condition has been documented in 350–400 families worldwide, most of which are consanguineous. The clinical features of this condition are the result of GHB accumulation due to inhibited GHB metabolism. Reports describe a range of clinical features including hypotonia, hyporeflexia, seizures, and ataxia.

There have been numerous reports of acute toxicity associated with the use of GHB, GBL, and 1,4-BD [4, 66–69]. The majority of these reports were initially related to GHB as this was the most commonly used drug, although more recently there have been increasing reports of acute toxicity related to the use of GBL. This not only mirrors the changes in the self-reported prevalence of use of GBL compared to GHB seen in the UK following the control of GHB, but also data from analysis of liquid samples seized at nightclubs [4, 66, 69]. Despite these changes, the pattern of acute toxicity is similar for GHB and

both related analogues as the toxicity is related to the GHB to which the analogues are metabolized. The only thing to note is that since 1,4-BD is metabolized to GHB predominately by alcohol dehydrogenase, in the presence of alcohol the onset of acute toxicity may be delayed as the alcohol will be metabolized preferentially over 1,4-BD [29–31].

There are a number of reasons why the true frequency of acute harm related to the use of GHB and its analogues is not known. Firstly, we do not have a true background rate of GHB and analogue use to compare the reported rates of acute toxicity. Secondly, not all patients who develop acute unwanted effects related to the use of GHB and its analogues will present to healthcare facilities for assistance. Some individuals who become drowsy will be looked after by “friends” until they get better. Finally, the recording of acute GHB or analogue toxicity by healthcare professionals may not always occur. For example, if there is no history of use or the healthcare practitioner is not aware of the clinical toxidrome associated with toxicity from GHB or its analogues, then the presentation may be attributed to ethanol or another depressant drug. Routine toxicological screening is not undertaken in the majority of emergency departments, as the results are generally not available in a time-frame to alter that individual patient’s management. In addition, where screening is undertaken, often this does not include GHB and its analogues. Therefore, the diagnosis of acute GHB or analogue toxicity is based upon the recognition of the clinical toxidrome associated with the overdose of GHB or its analogues.

In a survey of 76 GHB users (defined as use within the last 6 months) in Sydney and Melbourne, Australia, 53% reported that they had at least one overdose related to the use of GHB (the study authors defined an overdose as “having lost consciousness, and unable to be woken up”) and 63% had seen another individual overdose on GHB [10]. Thirty three percent of those who had overdosed had done so on more than three times; individuals who had previously overdosed on GHB thought they more likely to overdose

again in the future compared to those who had never overdosed (33% compared to 6%, $p < 0.05$). Those individuals who had overdosed on GHB had used for longer (median years of GHB use: 2 compared to 1 year, $p < 0.001$), used more times (median number of times ever used: 35 compared to 7, $p < 0.001$), and used more frequently (median number of days in last 6 months: 7 compared to 3, $p < 0.01$). In addition, there was an increased frequency of overdose amongst more frequent users; of those who had used >15 times, 75% had overdosed at least once. The most common reasons study participants gave for their last overdose were too much GHB taken (37%) and GHB stronger than usual (21%); whereas few participants identified too frequent dosing (8%), use with alcohol (8%), or lack of knowledge (0%) as contributing factors. Interestingly, when considering why others overdosed on GHB, too frequent dosing (15%), use with alcohol (17%), and lack of knowledge (22%) were more commonly reported. Setting of use appeared likely to impact on whether an individual gets medical attention or is taken to hospital – dance party/club 50%, public place 33%, and private house 19%; this is important in terms of education for individuals around GHB overdoses. The most recent 2015 Global Drugs Survey, formerly known as the MixMag survey, asked over 1,000 GHB users (exact number was not reported) about previous issues related to the use of “G” (GHB or GBL) [70, 71]. Of those who participated, “1 in 5” reported that they had passed out on “G” in the last year. In the European Drug Emergencies Network (Euro-DEN) project, of the 5,529 presentations to the 16 cities in 10 European countries between 1st October 2013 and 31st September 2014, 711 (13%) involved the use of GHB and/or GBL [72]. Overall, GHB/GBL was the fourth most common drug associated with an emergency department presentation after heroin, cocaine, and cannabis. There was significant geographical variation in the presentations where GHB/GBL had been used, with nearly 92% of cases being in the London, UK; Oslo, Norway; and Barcelona, Spain centers.

There are certain behaviors that have been associated with a higher-risk of hospitalization associated with the use of GHB. In a survey of 131 individuals, 26 reported the need for hospital treatment on at least one occasion for GHB-related toxicity/adverse effects [73]. The study authors had ten predefined high-risk behaviors, and participants were asked to determine whether any of these contributed to the need for hospital treatment. Of these ten predefined behaviors, four were associated with significantly increased risk of hospital treatment: (i) using GHB with ethanol – done by 58%, odds ratio (OR) of requiring hospital treatment 5.2 (95% CI 1.7–16.1); (ii) driving under the influence of GHB – done by 29%, OR of requiring hospital treatment 3.2 (1.3–7.8); (iii) use of GHB to treat withdrawal symptoms – done by 17%, OR of requiring hospital treatment 2.9 (1.1–7.9); (iv) co-use with ketamine – done by 23%, OR of requiring hospital treatment 2.7 (1.1–6.7). Certain high-risk behaviors were associated with certain population groups: (i) sex under influence of GHB was associated with being male, aged >30 years old or gay/bisexual/transgender; (ii) use of a GHB analogue or precursor was associated with being male; (iii) driving under influence was associated with being male; and (iv) use of GHB on their own was associated with being a non-LGBT individual.

The clinical features of acute GHB and analogue toxicity have been well described in five large case series totally 585 patients from London, UK (158 patients); Zurich, Switzerland (65 patients); San Francisco, USA (88 patients); Barcelona, Spain (104 patients); and Melbourne, Australia (170 patients) [4, 69, 74–76]. Overall, the commonest clinical feature seen in all of these case series was neurological depression; other commonly seen clinical features included bradycardia, hypotension, and mild hypothermia.

There was variability in the concurrent use of other recreational drugs in these case series, with 28–78% reporting use of other recreational drugs [4, 69, 74–76]. The most commonly reported co-used substances were stimulants [London – methylenedioxymethamphetamine (MDMA)

21% and cocaine 34% of presentations; San Francisco – Amphetamine 17% and MDMA 14%; Zurich – MDMA 18%, Cocaine 15% and Amphetamine 8%; Barcelona – Amphetamine derivatives 43% and cocaine 25%; Melbourne – MDMA 37% and methamphetamine 24%]. Not only it is possible that some of the clinical features reported to be associated with acute toxicity related to the use of GHB or its analogues may be “masked” by these stimulant substances, but they could impact on severity of acute toxicity (discussed in more detail in the management section below). An example would be the expected bradycardia from acute GHB toxicity may not be present in an individual who has co-used a stimulant recreational drug. In addition, it is possible that the acute GHB toxicity may be accentuated by concurrently used sedative substances. The co-use of ethanol was higher than would be expected (between 22% and 73% of presentations there was reported co-use of ethanol with the lowest co-use in the Australian case series and the highest co-use in Spanish case series), particularly as many individuals report that they are aware of the risks of co-use of sedatives with GHB or an analogue. In addition, there was a lower reported use of other sedatives (benzodiazepines 3%, opioids 1–2%, and “sedatives” 2–8%). Previous reports have suggested that co-use of ethanol concurrently with GHB is more likely to be associated with the presence of severe GHB-related complications [69, 73, 77]. In the Swiss case series, co-use of ethanol with GHB/GBL was associated with a significant increased risk of agitation/aggression (9 out of 31 (29%) patients) compared to those with sole GHB/GBL use (2 out of 34 (6%) patients, $p < 0.02$) and a nonsignificantly increased risk of vomiting (combined GHB/GBL-Ethanol use: 12 out of 31 (38%) patients; sole GHB/GBL use: 8 out of 34 (24%) patients, $p < 0.07$) [69]. However, in this case series the co-use of ethanol with GHB/GBL was not associated with any worsening of the level of consciousness or the duration of coma compared to lone GHB/GBL use. In the placebo-controlled double-blind study of GHB and ethanol taken alone or in combination discussed in more detail previously in the

pharmacology section, there was a higher rate of adverse effects in the GHB-ethanol co-ingestion arm compared to either the lone ethanol or lone GHB arm [33]. The increased risk of adverse effects included: Vomiting – 6 cases in the combined GHB-Ethanol arm, 1 case in lone GHB arm, and 1 case in lone ethanol arm; Hypotension – both episodes of significant systolic hypotension (SBP 71–73 mmHg) occurred in the combined GHB-Ethanol arm; Hypoxia – all three treatment arms lead to reduced oxygen saturations (hypoxia) compared to placebo for the 4-h duration of observation, although the reduction ($-2.12 \pm 0.34\%$) seen in the combined GHB-Ethanol arm was significantly greater than the lone GHB arm ($p = 0.0027$) and lone ethanol arm ($p = 0.013$). Although there was no statistical difference in the pharmacokinetic profile of GHB when taken either alone or in combination with ethanol, there was a nonsignificant increase in both the C_{max} (16% increase) and half-life (29% increase) which could possibly explain the increased adverse effects in the combined GHB-Ethanol group.

The most common clinical feature was a reduced level of consciousness – all patients in the Spanish cohort had coma (Glasgow Coma Score (GCS) ≤ 8) on the scene of use [74]. Although the time of transfer from the scene of acute toxicity to the Emergency Department (ED) was not reported, 50% had recovered to a GCS > 8 by the time of arrival in the ED. The overall rate of “nonresponsive coma,” typically defined as a GCS of 3/15, in the large case series ranged from 16% to 34% [4, 69, 74–76]. Despite this proportion of individuals with a “nonresponsive coma,” overall only 3–17% required endotracheal intubation for management of their airway.

Overall, in the previous published case series of acute toxicity the reported rates of intubation were 2–12% [69, 74, 76]. In the Australian case series, of those patients with a “low GCS” (not specifically defined) on arrival at the Emergency Department, 87% were not intubated. Overall in this case series 87 (51%) had an “airway intervention” – this included an oropharyngeal airway (51 patients), nasopharyngeal airway (23 patients),

and/or endotracheal intubation (13 patients) [76]. It is not possible to determine what proportion of those who were intubated failed the use of an airway adjunct prior to intubation from the information reported. It should be noted that – unlike patients presenting with a GCS ≤ 8 for other medical reasons, who are commonly intubated – of the 33 patients with a GCS of 3/15, only 33% were intubated and the remaining 67% were managed conservatively without the need for intubation [74, 75]. Additionally, given the rapid recovery from acute GHB or related analogue toxicity, patients may regain consciousness rapidly; in the Australian case series the median time from admission to the Emergency Department and recovery of GCS to 14 or 15 was 112 min [76]. This rapid recovery of neurological depression can mean that those who have been intubated in the Emergency Department often wake rapidly and can be extubated prior to transfer to a Level 2/3 bed; in the US case series, 2 (18%) of the patients intubated for a reduced level of consciousness woke up sufficiently to be extubated and discharged direct from the Emergency Department [75]. In the Australia case series, where 13 (8%) patients were intubated (1 prehospital and 12 in the Emergency Department), 9 (69%) were successfully extubated in the Emergency Department and discharged directly home [76].

In a case series of 21 individuals with suspected acute GHB toxicity at rave parties that were screened for the presence of GHB, 6 had no GHB detected although they had blood alcohol concentrations between 2.5 and 3.2 mg/L [78]. The median time that individuals had a GCS of ≤ 8 was 90 min (30–105 min) and the median time from GCS ≤ 8 to a GCS ≥ 12 was 30 min (range 10–50). Once a patient had a GCS of >9 , their GCS did not drop below 8 again. The median GHB concentration when patients had their last GCS ≤ 8 was 183 $\mu\text{g/L}$ (100–321). However, by the time the patient had woken up the median concentration had fallen to only 150 $\mu\text{g/L}$ (78–256), suggesting that patients woke up while still having significantly high GHB concentrations. Serial serum GHB concentrations were measured in 15 patients who presented with

acute GHB toxicity to an Emergency Department in San Francisco, the initial serum GHB concentration in the whole study population [median 180 mg/L, range 45–295 mg/L] was comparable to that in the 11 who developed a GCS of 3 [median 193 mg/L, range 124–242] [79]. Peak GHB concentrations did not correlate with time to awakening, and when patients had recovered to a GCS of 15, serum GHB concentrations were declining from initial peak concentrations on arrival but were still in the range 75–150 mg/L (range 0.5–2.5 h after initial concentration).

The range of patients who had vomiting in these series was between 16% and 31% [4, 69, 74–76]. The effect of co-use of ethanol with GHB was reported to nonsignificantly increase the risk of vomiting (39% in those with co-used ethanol compared to 24% in those who had not co-used ethanol) [69]. Typically, vomiting in the context of a reduced level of consciousness, in particular those with a Glasgow coma scale (GCS) of ≤ 8 , is thought to increase the risk of aspiration due to the lack of protective airway reflexes. Of the 28 patients with vomiting in the Australian case series, 20 had vomiting with reduced GCS (defined as ≤ 13), only 2 were intubated [76]. In a US case series of 88 patients, vomiting typically occurred either during the emergence from the coma and/or during periods of fluctuating levels of consciousness during recovery from the acute overdose [75]. Of the 22 patients who had vomiting, there were no documented episodes of pulmonary aspiration, despite 85% of these individuals having an initially GCS of ≤ 8 .

The reporting of cardiovascular toxicity in the case series can be difficult to interpret due to the high proportion of patients who have co-used other substances, particularly stimulants, which may have their own acute cardiovascular toxicity. Bradycardia was reported in between 20% and 38% across the published series, although the definition of bradycardia varied between case series between <55 and <60 beats per minute (bpm). There was a significant correlation between level of consciousness and bradycardia [69]. Patients with bradycardia (defined as heart rate ≤ 55 bpm) had a median initial GCS score of 4 compared to a median GCS of 9.5 in those

without bradycardia [75]. Hypotension has also been reported in a number of patients, although generally this was associated with the co-use alcohol and/or other recreational drugs and/or the presence of other cardiovascular or neurological toxicity [74, 75]. For example in the US case series, all 10 patients with hypotension had taken alcohol and/or at least one other recreational drug and six had concurrent bradycardia [75]. Similarly, in the Spanish case series, all seven patients with hypotension had a GCS ≤ 7 on arrival to the Emergency Department, all had taken alcohol and/or at least one other recreational drug and four patients were also bradycardic [74].

Seizures were documented to have occurred in 2–10% of the five large case series [4, 69, 74–76]. Although not formally reported in the case series, it was commented that often the “seizures” occurred in the prehospital setting and/or were unwitnessed by medical professionals; in the Swiss case series where 5 (8%) patients had seizures, only 1 was witnessed by hospital staff within the Emergency Department [69]. It is known that GHB and its analogues can cause myoclonic jerks, with 3% and 4% of patients in the Spanish and Australia case series reported to have myoclonus, respectively [74, 76]. Therefore, it is not possible to determine what proportion of the “seizures” were in fact misinterpreted “myoclonic jerks.”

Chronic Dependency and Withdrawal

The prevalence of GHB and related analogue dependency and associated physical withdrawal on cessation of use is currently not clearly understood. This lack of understanding was highlighted in the 2008 European Monitoring Centre for Drugs and Drug Addiction “emerging trend case report” on GHB and its precursor GBL, where the EMCDDA noted that there was no pan-European system for reporting or collating data on the frequency of GHB or related analogue dependency [80].

As discussed earlier, GHB has been used in the management of alcohol dependency, which provides some data on the misuse of GHB in this

setting and the potential for GHB dependency developing. In an Italian multicenter study, 179 patients with alcohol dependency were recruited from 19 centers and treated in an open label study with 50 mg/kg GHB three times per day for 24 weeks [81]. Of the 109 participants who completed the study, 11 (10.1%) showed “craving” for the GHB and voluntarily increased their doses, in some cases to six to seven times the recommended treatment dose, to obtain the desired anxiolytic and hypnotic effects. Gallimberti and colleagues reviewed their use of GHB (up to 300 mg/kg/day in divided daily doses) in the management of Italians with dependence from psychoactive substances (138 alcohol dependent, 23 opiate dependent, and 34 polydrug dependent individuals) to determine the abuse potential of GHB in these settings [3]. Of the 195 patients recruited into these two studies, 29 (14.9%) were thought to show “GHB abuse.” The authors characterized these into three distinct groups: Group 1 7 patients who self-increased the dose of GHB up to twofold recommended dose as they felt the prescribed dose was too low; Group 2 12 patients who increased the dose of GHB in a similar fashion, but this was associated at times with episodes of acute intoxication; Group 3 10 individuals who appeared to have GHB dependency with similar behaviors as seen in those patients with alcohol and/or drug dependency (constant engagement with searching for the euphoric, empathogenic, hypnotic, anxiolytic, and/or antidepressant effects of GHB), with individuals reporting that “life without GHB was unacceptable.” Overall, this equated to GHB dependency prevalence of approximately 5%.

More recent studies have suggested that individuals with previous heroin or cocaine dependency may be at greater risk of developing GHB dependency when it is used for the management of alcohol dependency [82]. Craving for and abuse of GHB was studied in an open label study of 50 mg/kg GHB three times a day for 3 months given to four groups of patients: Group 1 – lone alcohol dependency (14 patients); Group 2 – alcohol dependency with previous heroin dependency (abstinent for >12 months) (10 patients); Group 3 – alcohol dependency with previous cocaine

dependency (abstinent for >12 months) (13 patients); or Group 4 – alcohol dependency on a current methadone replacement treatment program (10 patients). There was no reported craving or abuse in the group 4 patients, and while 2 (14.3%) of patients in Group 1 had cravings for GHB, there was no reported abuse. However, in those patients with previous cocaine dependency (Group 3) although reported rates for craving were not significantly different from those without previous cocaine dependence (38.5% compared to 14.3%, $p = 0.1$), there were significantly high rates of abuse (38.5% compared to 0%, $p = 0.01$). Those patients with previous heroin dependency had significantly higher rates of craving (90.0%, $p < 0.001$) and abuse (60.0%, $p < 0.001$) compared to those without. It has been postulated that chronic heroin and/or cocaine use can lead to down-regulation of dopamine D1 and D2 receptors and that these changes can persist for prolonged periods after cessation of use of the drug [82–85]. In addition, chronic cocaine use can lead to reduction in GABA-B receptor activity in the meso-cortico-limbic areas, reducing dopamine release and potentially predisposing individuals to craving and abuse for GHB since this acts through GABA-B receptors [82, 86, 87]. There are no published data on whether those individuals who are previous or current users of stimulant or other recreational drugs have a higher prevalence of GHB and related analogue dependency.

The first case of GHB-related dependency was reported in the medical literature in 1994 [88]. A 30-year-old female patient had been consuming 25 g of sodium oxybate (which is GHB) per day in five divided doses for approximately 2 years; she reported that use was associated with “feelings of relaxation, increased libido and striking euphoria.” Three months prior to presentation, she had abruptly reduced her daily intake to 10 g per day (2 g five times per day) with “anxiety” that lasted for approximately 1 week. On six occasions following the reduction to 10 g she attempted to stop use completely; on each occasion, within 12 h of her last dose, she developed tremor and anxiety. Following review in a drug treatment facility she was told to cease GHB use but was not provided

with any pharmacological intervention to manage the withdrawal symptoms; she subsequently was reviewed following a period of abstinence and reported that she had had insomnia, tremor, and anxiety for 12 days following cessation of use.

The same drug treatment facility reported a case series of eight individuals with GHB use related issues in 1997, five of these eight individuals had symptoms suggestive of GHB-dependency and withdrawal on cessation of use [89]. One of these had been previously published and is discussed in detail above [88]. The other individuals were one female and three males aged between 31 and 40 years old using GHB to ameliorate effects of other stimulant recreational drugs (1 individual), euphoria (1), hypnotic effects (2), or anabolic effects (3). All had histories of using increasing amounts of GHB per day secondary to developing tolerance and decreasing effects. Symptoms on cessation of use included insomnia, muscle cramps, anxiety, and tremor; only one individual required pharmacological treatment with a single dose (30 mg orally) of phenobarbital to manage these withdrawal effects.

Since then, there have been numerous published case reports and series of dependency developing following the chronic use of GHB and its analogues [46, 94–102]. It is not possible to determine whether there is a difference in the risk of dependency developing between the different GHB-related analogues, and it is likely that the difference seen in the reported cases of dependency (initially predominately GHB, with increasing numbers related to GBL), reflect the changes described earlier in the change in the use and availability of GHB and GBL over time. Similarly, the limited number of 1,4-BD related cases mirrors the significantly lower self-reported prevalence of use of this compared to both GHB and GBL.

Dependency to GHB and/or its analogues typically occurs in individuals who have been using for several months or years and usually multiple times throughout the day and night. Typically, individuals will have started as “weekend” recreational users associated with clubbing, parties, and sexual liaisons. Over time, their use increases

usually with doses between infrequent events to help with sleep and/or adverse effects of stimulant recreational drugs before they become daily users of GHB or its analogues [1, 93, 101]. The estimated daily doses of GHB or related analogues being used varies between individuals but typical reported ranges are 18–100 g and 10–60 g for GHB and GBL respectively [101]. Based on the literature and our own clinical experience, the majority of patients have been using for a minimum time period of 2–3 months and are using at least three to four times per day [1, 46, 92, 94]. In the case series of 38 GHB/GBL-related withdrawal cases, the authors concluded that thrice daily dosing was the minimum frequency associated with physical dependency and withdrawal and the mean duration of use prior to dependency was 1.3 years [101]. However, the majority of those who have dependency are using considerably more frequently, typically every 1–2 h throughout the day, and may be waking at night to redose due to prevent onset of withdrawal symptoms. In addition to escalation of frequency of use, typically individuals may have a history of escalating doses used [46]. This can be potentially risky since unlike alcohol, benzodiazepines, and opioids, individuals do not develop the same tolerance to GHB as with these other drugs, and so they are still at the same risk of acute overdose and associated toxicity.

Although, as noted, dependency typically develops after prolonged regular use, there are examples of dependency developing after shorter periods of high-frequency use. A female who presented to an Emergency Department with symptoms suggestive of GHB withdrawal; she had started using GHB 8 days previously as a “sleep aid and intoxicant” and the dosing rapidly escalated to “3 ounces” of GHB every 2–3 h “round the clock” [103]. This phenomenon has been described for alcohol, benzodiazepines, and opioids where high-dose and/or high-frequency use over a short period of time can be associated with the rapid development of dependency and withdrawal upon cessation of use.

The clinical features of GHB and its analogue withdrawal are similar to those seen with ethanol

and/or benzodiazepine withdrawal and acute stimulant recreational drug/novel psychoactive substance toxicity. Therefore, without a clear history of regular dependent use of GHB or related analogue, which can be difficult to obtain at the time of presentation if the patient has florid withdrawal symptoms, it is often difficult to make a definitive diagnosis of GHB withdrawal at presentation. From a clinical perspective, as discussed under the management section below, this often does not alter management as currently the mainstay of treatment is benzodiazepines, which often is the initial treatment for all of these clinical scenarios.

The onset of withdrawal often is very rapid following the cessation of use, and individuals may develop symptoms of withdrawal within a few hours of last use and they can rapidly deteriorate becoming severe within a short period of time. In a case series of eight individuals presenting with GHB withdrawal, the onset of symptoms occurred within less than an hour to 6 h after last dose [46]. In a series of 38 cases of unplanned GHB/GBL related acute withdrawal, most presented within 24 h of their last dose [101]. Some have suggested that there is a difference in time to onset of withdrawal between the different analogues (GHB 7.5 h, 1,4-BD 6 h, GBL 72 h). However, the number of cases in the GBL and 1,4-BD groups were much less than the GHB group and additionally, these cases were from the published literature only [93]. In our experience, and based on the pharmacology of these compounds, there is no reason to suspect that there should be any difference between them in terms of time to onset of withdrawal. In addition, it is recognized that individuals may develop withdrawal when recovering from an acute GHB/GBL overdose as their GHB concentrations fall. This is different from alcohol and benzodiazepine withdrawal where there is often a longer time-lag of many hours between cessation of use and onset of severe withdrawal symptoms [46]. It is also important to be aware that some individuals may present through other routes than in unplanned acute withdrawal or to drug treatment services seeking planned withdrawal. There has been a

Table 1 Typical clinical effects by organ system seen in acute GHB or related analogue withdrawal

Organ system	Symptoms
Cardiovascular	Tachycardia
	Hypertension
Gastrointestinal	Nausea and vomiting
	Diarrhea
Neuropsychiatric	Anxiety
	Agitation and aggression
	Hallucinations (auditory, visual, or tactile)
	Insomnia
	Delusions
	Paranoia
	Tremor
	Seizures; cravings
Other	Confusion; muscle twitches
	Diaphoresis; rhinorrhoea

reported case of a 32-year-old male admitted following a road traffic accident and associated pelvic fractures under an orthopedic team where the issue of GHB-dependency was not detected on admission, and the patient subsequently started to develop features of withdrawal on the second day of his hospital admission [104].

The common clinical features of GHB and related analogue withdrawal are summarized in Table 1 [1, 46, 90–107]; there is a predominance of neuropsychiatric effects during withdrawal, particularly agitation and aggression, delirium, florid hallucinations, and delusions. It has been suggested that the severity of neuropsychiatric effects seen in GHB and related analogue withdrawal is similar to that seen with acute baclofen withdrawal. Some authors have reported that the neuropsychiatric effect can have a longer duration than the physical symptoms and may persist for up to 14 days after the physical symptoms have settled [105].

A previous review of 31 patients who presenting to our clinical toxicology service with acute GHB-related withdrawal confirmed the predominance of neuropsychiatric symptoms [107]. The most common neuropsychiatric symptom was anxiety (in 61% of presentations); other symptoms included agitation (48%), tremor

(39%), hallucinations (36%), paranoia (19%), confusion (16%), amnesia and delusions (both 13%), and sexual disinhibition and insomnia (both 10%). This is similar to a case series of 38 unplanned GHB/GBL withdrawal, where the frequency of clinical features were: tremor (74%), tachycardia (66%), anxiety (61%), hallucinations (55%), delusions/paranoia (37%), delirium (53%), insomnia (53%), diaphoresis (32%), hypertension (29%), and nausea/vomiting (18%) [101]. In a further case series of 57 patients identified from 27 published articles (36 GHB-related withdrawals, three 1,4-BD and 18 GBL), there frequency of symptoms experienced was broadly similar across the three different analogues [93].

Based on a case series of seven patients, the time course of effects of acute GHB withdrawal has been outlined [46]. This can be described as three phases: early (1–24 h), “progressive” (1–6 days), and then episodic during recovery (7–14 days). Predominant early effects include: severe-anxiety, restlessness, and insomnia; moderate – nausea and vomiting; mild – tremor, tachycardia, hypertension, and diaphoresis. Predominant “progressive” effects include: severe – anxiety, restlessness, insomnia, confusion, delirium, and hallucinations; moderate – tremor, tachycardia, hypertension, and diaphoresis; mild – nausea and vomiting. During the recovery phase, the effects typically are reducing, with none graded as “severe”; moderate symptoms include anxiety, restlessness, insomnia, confusion, and hallucinations and mild symptoms include diaphoresis, tachycardia, and hypertension. Overall the mean duration of withdrawal has been reported to be 8–9 days (range 3–15 days), which is longer than that reported for acute alcohol withdrawal (typically 3–7 days) [93, 101].

Not only does the pattern of clinical features vary between patients, it has been reported to be variable within individual patients who present with recurrent episodes of dependency and/or withdrawal [98]. A 29-year-old female with a history of 4 years of GHB use, which escalated from recreational use to daily use between 48 and 96 g per day, presented with four episodes of

withdrawal over a 2-year period. Some clinical features were present on all or three of the four withdrawal episodes (anxiety, tremor, insomnia, nausea and vomiting, vivid dreams, and fatigue), whereas other clinical features were only present on one or two of her withdrawal episodes (hypervigilance, tachycardia, paranoid delusions, irritability and somatic, visual or auditory hallucinations). The frequency/occurrence of clinical features did not appear to be related to the dose of GHB being used prior to the episode of withdrawal. Additionally, it is generally accepted that an individual who has had previous episodes of GHB or related analogue dependency and associated withdrawal on cessation of use typically develops recurrent dependency within a much shorter time-frame than the time taken to develop their initial dependency.

In terms of severe effects associated with GHB or related analogue dependency and withdrawal, there is a single case report of Wernicke-Kosakoff Syndrome in a 23-year-old female with a history of using GHB for last 18 months [108]. In addition, she had alcohol excess since age 15, which stopped when she started using GHB. Similar to other cases, her dose frequency of GHB use increased due to developing tolerance, and self-initiated periods of abstinence failed due to severe insomnia, paranoia, tremors, and restlessness; she would often self-medicate with alcohol to help herself sleep and prevent the withdrawal symptoms occurring. She was reviewed in hospital the day following a car accident (having been seen and discharged from an ED on the day of the car accident) and she was paranoid, hallucinating (visual and auditory), tremulous, confusion/disorientated, incoherent, and had "crossed eyes." She was managed with thiamine, benzodiazepines, and chlorpromazine. The next day she was reviewed by a neurologist and noted to be drowsy, dysarthric, have a poor memory, nystagmus with ocular cranial nerve palsies, and was ataxic. A diagnosis of Wernicke-Korsakoff Syndrome related to GHB use was made. One month following her withdrawal, the neurological signs had resolved and there was no evidence of cognitive impairment. It

should be noted that while this was attributed to her GHB dependency, it is more likely to be related to her ongoing ethanol use and poor nutritional intake (when using, she would often go without food for several days and prior to this particular admission, she had not eaten for over a week).

To date there has only been one reported death associated with the management of GHB or related analogue dependency and withdrawal, although the circumstances surrounding the death and the relationship to the GHB withdrawal management are unclear [46]. A 24-year-old male presented with a 12-month history of GHB use, with dose frequency escalating to every 30 min to prevent the onset of GHB withdrawal hallucinations. On presentation, he complained of nausea, vomiting, diarrhea, feeling "weak and swollen," diplopia with blurred vision, shortness of breath, urinary frequency, and blackouts for the last 2 months. He was managed with lorazepam for agitation, although he developed tachycardia, visual hallucinations, agitation/combativeness, and tremors. His initial admission was complicated by a right lower lobe pneumonia required ventilatory support during which time he was sedated with propofol. Following extubation he remained confused and was hallucinating requiring physical restraint with benzodiazepines and antipsychotic (not specified) medication. He appeared to be improving on day 12 postadmission, so his lorazepam dose was tapered. However, on the evening of the following day he had an "episode of spontaneous, generalized, spastic muscular contractions with an upward gaze" which was followed by "cardiac arrest." Autopsy demonstrated pulmonary oedema, cardiomegaly, left ventricular hypertrophy, and coronary artery disease. The cause of death was reported as "a complication of GHB withdrawal resulting from chronic substance abuse." It is not possible to determine the significance of the initial presentation of GHB dependency in the events that happened a number of days after presentation, and it is unlikely that this death was directly, if at all, related to the GHB dependency and withdrawal.

Indications for Admission to ICU

Acute toxicity	Prolonged reduced level of consciousness not improving after 2–3 h of onset
	Vomiting and risk of aspiration requiring endotracheal intubation for airway protection
	Toxicity related to the co-use of other drugs requiring monitoring and/or treatment in a high dependency (HDU, Level 2 bed) or Intensive Care Unit (ICU, Level 3 bed) environment
	Cardiovascular instability requiring treatment in an HDU or ICU environment
Withdrawal cases	Patients with agitation/aggression not manageable in a Level 1 bedded area
	Requirement for intravenous benzodiazepine treatment if not available in a general ward area (i.e., requires a Level 2 or Level 3 bed for administration)
	Requirement for IV barbiturates and/or other sedative treatment where intubation and ventilation is indicated

Diagnosis

It is possible to measure GHB concentrations in a variety of different biological matrices [1]. Urine is generally considered the biological matrix of choice for analysis, due to the longer time in which GHB can be detected [32]. Analyzing for GHB in biological samples using a variety of different analytical techniques is challenge for a number of reasons. Firstly, since GHB is produced endogenously as a breakdown product of GABA, the detection of GHB in the blood, urine, and/or another biological matrix does not confirm use. Therefore, there is the need to use a “threshold concentration” to differentiate between the detection of endogenous production of GHB from that following use. Broadly speaking, a concentration of 10 µg/mL has been accepted in antemortem urine as indicating use, as endogenous concentrations are typically around 1 µg/mL [109–115]. Since GHB concentrations in blood are lower

than those in urine, a concentration of between 1 and 5 mg/L has been suggested as indicating an exogenous GHB source when interpreting blood analyses [116, 117]. In addition, concentrations of GHB in both blood and urine specimens can increase with both increased time between collection and analysis and if samples are stored at room temperature prior to analysis [118–123]. This is thought to be less of an issue with urine, since endogenous concentrations above the 10 µg/mL cut-off have not been reported [110, 119, 120]. However, concentrations in blood greater than 100 µg/mL have been detected in postmortem samples definitively not related to GHB or related analogue use. The reasons for this extensive ex vivo production is not understood, but in some part may relate to bacterial metabolism [121, 122]. Therefore, it is important that samples collected for GHB or related analogue detection are appropriately stored and rapidly analyzed to prevent the possibility of a false-positive result. Secondly, GHB is metabolized to carbon dioxide through the Krebs cycle, meaning approximately only 1% of GHB is eliminated in urine [14, 15, 124]. In addition, with this extensive metabolism, there is no metabolite of GHB or its analogues that can be detected in biological samples for longer than the parent molecule. Typically, this means that GHB or related analogues can only be detected in biological samples for around 12 h following use, so samples need to be collected as soon as possible following use to prevent a false-negative result [14].

There are a range of different analytical techniques available to detect both GHB and its related analogues. These include colorimetric and enzymatic assays, gas chromatography with flame ionization detection (GC-FID) or mass spectrometer (GC-MS), liquid chromatography quadrupole mass spectrometer (LC-MS/MS), gas chromatography isotope-ratio mass spectrometry (GC-IRMS) [14, 111, 113, 125–134]. There are some caveats with these different analytical methods. Firstly, there are differences in the limits of detection (LOD). For example, colorimetric and enzymatic based methods have an LOD of 100 µg/mL and 50 µg/mL, respectively,

whereas GC-FID, GC-MS LC-MS/MS have LODs of 0.01–5 µg/mL. This means that some analytic methods may “miss” samples with concentrations above those associated with endogenous GHB but below their LOD, giving a false-negative result. Secondly, some analysis may be direct detection of GHB, GBL, and 1,4-BD themselves (e.g., LC-MS) or for GHB through derivatization (e.g., GC-FID, GC-C-IRMS), whereas other techniques require the conversion of GHB (and 1,4-BD) to GBL prior to analysis (e.g., GC-FID). Analysis through conversion to GBL precludes determination of exactly which analogue was used. Finally, it should be noted that these analytical techniques may not be available in every acute hospital setting and/or may not be available at all times (i.e., outside working hours), meaning that the analytical results may not be available in a time-frame that would alter an individual patients’ management.

Therefore, the diagnosis of both acute GHB or related analogue toxicity and chronic dependency and withdrawal is largely based on history, symptoms, and/or signs, rather than analytical confirmation. A survey of professionals with training related to GHB intoxication, and professionals without training, compared their ability to determine which of a number of statements related to acute GHB intoxication indicated significant risk of potential failure in vital physical function [135]. The most highly rated amongst all 105 respondents were cardiac arrest, coma, hypoxia, generalized convulsions, slow respiratory rate, and slow heart rate. Additionally, there was no significant difference between those with and without training, suggesting that non-specialists were able to detect patients at significant risk.

Management of Acute Toxicity

The majority of patients with acute GHB toxicity start to recover with improvement in their level of consciousness within 2–3 h of onset, and therefore the management as discussed further below is largely supportive.

In vitro activated charcoal GHB adsorption studies demonstrate up to 84% adsorption of a dose of 800 mg GHB with an in vivo equivalent dose of 100 g activated charcoal (the standard 50 g dose of activated charcoal was associated with approximately 70% adsorption) [136]. However, since the onset of acute toxicity is rapid and the majority of individuals present with a reduced level of consciousness, in clinical practice there is unlikely to be any benefit to activated charcoal administration or any other form of gastric decontamination.

Although not reported in most case series, the majority of patients recover sufficiently quickly in the Emergency Department to be discharged directly from the ED. For example, in the UK case series of 158 GHB/GBL patients, only 12 (8%) were admitted to hospital [4]. In the Spanish case series, the mean time to regain complete consciousness was 66 ± 55 (range 1–360) minutes [74]. In a cohort of 66 individuals with acute GHB toxicity, mean time to recovery of consciousness was 146 ± 93 (range 16–389) minutes in 55 nonintubated patients compared to 274 ± 94 (161–439) minutes in the 11 intubated patients. The authors acknowledged that this increased time to recovery in the intubated patients may reflect the use of sedatives during intubation [75]. In addition, the time to recovery related to initial presenting GCS on arrival in the ED was: GCS 3–5 177 ± 109 (31–389) minutes; GCS 6–8 134 ± 75 (16–268); GCS 9–13 116 ± 81 (16–260) minutes. In the 158 patients in the London series, the median length of hospital stay was 2.8 (IQR 1.9–4.0) hours, and those presenting with a low GCS (defined as ≤ 8) had a significantly longer hospital stay (median length of stay 3.8 (2.4–7.5) hours) [4]. The co-use of alcohol with GHB was not shown to increase the duration of coma compared to those with GHB/GBL use alone [69]. However, co-use of GHB/GBL with stimulant recreational drugs (e.g., cocaine, MDMA, amphetamine) was associated with more severe (GCS of 3 in 65% of those with co-used stimulants compared to 20% in lone use, $p < 0.001$) and prolonged (time to recovery 155 ± 60 min compared to 94 ± 54 min, $p < 0.02$) coma. The rate of ICU admission

from the ED for acute GHB/GBL toxicity is 4–7% [4, 76]. As expected, admission to ICU was associated with an increased length of stay of (median 18 (IQR 10.1–39.2) hours) compared to those directly discharged from the ED (2.4 (IQR 1.7–3.0) hours) [4]. Additionally, the length of stay following attendance at the ED has been shown to be related to: (i) degree of reduced level of consciousness on presentation to the ED: those with low GCS (defined as 3–8) had a median length of stay of 219 (interquartile range [IQR] 188) minutes compared to 174 (IQR 125) minutes in those with a high GCS (defined as 9–15), $p < 0.001$; and (ii) whether the patient was intubated: those with intubated had a median length of stay of 460 (IQR 506) minutes compared to 192 (IQR 132) minutes in those not intubated, $p < 0.001$ [76]. In addition, those individuals who had a low GCS (defined as 3–8) and were intubated had a significantly longer length of stay compared to those with a low GCS who were not intubated (intubated 392 (IQR 417) minutes compared to nonintubated 209 (IQR 161) minutes, $p = 0.001$).

Based on the information discussed in the acute toxicity section above, the management of acute GHB or analogue toxicity is largely supportive care. Given the short duration of the reduced level of consciousness, the need for intubation is debatable and often the recommendation for endotracheal intubation for airway protection and/or ventilatory support is related to other indications rather than just the reduced level of consciousness. It should not be assumed that those patients with a reduced level of consciousness have significant respiratory depression and associated respiratory acidosis as to dictate endotracheal intubation for respiratory management. While all nine patients in the US study with a pH less than 7.30 had a reduced level of consciousness (six had a GCS of 3 and three had a GCS of 6), of those 21 with a pH ≥ 7.31 , nine had a GCS of 3, and 12 had a GCS of between 4 and 14 [75]. Therefore, the decision to intubate should not solely be made on the basis of level of consciousness. In patients where there is vomiting associated with a reduced level of consciousness, then endotracheal intubation

may be appropriate to prevent aspiration. However, in nonintubated patients with acute toxicity with GHB and its analogues, vomiting in those with the greatest degree of neurological compromise was not associated with pulmonary aspiration, suggesting that “prophylactic” intubation in case of vomiting is not indicated [75]. Evidence from our own clinical practice, and that reported in the other large case series, indicates that routine intubation of patients with acute GHB or analogue toxicity is not indicated unless there is vomiting in patients with a reduced level of consciousness, recurrent seizures, or another clinical indication for intubation (Grade IIb/III recommendation).

There is currently no specific antidote to reverse the acute effects of GHB or its analogues. Previously it has been suggested that naloxone and/or flumazenil may be beneficial in the management of patients with acute GHB or analogue toxicity. In one case series of 104 patients, 14% were empirically administered naloxone and/or flumazenil with no response in the level of consciousness [74]. We believe that the only role for naloxone in the management of these cases is where diagnosis of GHB or analogue toxicity is not certain and to exclude opioid toxicity as a potential cause for the clinical features. However, in patients where acute GHB or analogue toxicity is clinically the most likely diagnosis, there is no pathophysiological or pharmacological basis for the routine use of naloxone, as the mechanisms of action of GHB and its analogues are different to that of opioids. Similarly there is no pharmacological basis for the administration of flumazenil, since this acts specifically on benzodiazepine receptors and therefore should not have an action to reverse GHB or analogue toxicity. Previously there have been suggestions that physostigmine, an inhibitor of acetylcholinesterase, could be beneficial in the treatment of acute sedative overdoses such as GHB. A structured literature review found that there was insufficient evidence to support the use of physostigmine due to limited published evidence and/or methodological flaws and confounding factors in the published case series [137]. In addition, there has been interest in the use of specific GABA-B

antagonists (e.g., SCH50911) in animal models to prevent and/or treat the respiratory depression seen following GHB administration [38], although this has not progressed into human clinical trials to date.

In terms of prevention of acute toxicity related to the use of GHB and its related analogues, the Global Drug Survey produced in 2014 a “Highway Code” for more safely using GHB and related analogues [138]. In the production of this, the authors surveyed over 850 “G” users with a number of suggested harm reduction methods and asked them how important they rated this (out of 10) in terms of reducing harm associated with use and the frequency that they utilized these methods to prevent harm from GHB/GBL. The most common harm-reduction method was using premeasured doses of GHB/GBL, thought to be of high importance (scored 9.1 out of 10) and done by 85% of users regularly. Other methods included avoiding alcohol (9.1, 70%), timing doses (8.8, 32%), setting limit on amount used (8.3, 56%), avoiding stimulants (7.2, 40%), and writing G on wrist so if they collapse responders can know what they have used (6.9, 2%). Some of these harm-reduction methods may be useful in discussing with patients prior to discharge to prevent overdose and associated acute toxicity in the future, particularly given the high self-acknowledged risk of future overdoses in individuals who have had a previous overdose.

Management of GHB and Related Analogue Dependency and Withdrawal

When an individual has been identified as potentially dependent on GHB or a related analogue, and therefore at risk of withdrawal on cessation of use, the management depends on the situation in which the patient has been identified. In those who have been identified within a hospital environment, these can be broadly divided into the following categories:

1. Not wanting to cease use at this time and able to continue to source GHB or related analogue

2. Wanting to stop use, not acutely withdrawing and able to continue to source GHB or related analogue
3. Wanting to stop use, not acutely withdrawing but unable to continue to source GHB or related analogue
4. Require admission for another medical reason
5. In acute withdrawal with or without delirium at the time of review

Individuals in Group 1 can be provided with information on local drug and alcohol treatment services and/or specialist drug treatment services for the MSM community and advised to engage with services when they feel that they wish to stop using. Those in Group 2 do not require admission for inpatient detoxification and again can be provided with information on appropriate local services. We recommend that both groups should be advised not to stop using prior to engagement with services so that their cessation of use can be medically supervised and appropriate pharmacological treatment provided as required. It is often possible on discussion with individuals in Group 3 that they can actually source GHB or related analogue until they can engage with an appropriate service for ongoing management. If this is truly not possible, they may require admission for observation and management of withdrawal. Individuals in Groups 4 and 5 require admission to hospital with appropriate pharmacological management for withdrawal.

A case-based vignette study of addiction specialists was undertaken in The Netherlands to try and more robustly identify biological, social, and psychological characteristics that help determine whether a patient should be offered inpatient or outpatient detoxification [139]. Twenty-one addiction specialists contributed 20 case vignettes of a range of severity of GHB detoxifications that they had previously managed. These case vignettes were then reviewed by a focus group (11 other psychiatrists and addiction specialists), rating them on a scale of -5 to $+5$, where -5 indicated with certainty that outpatient detox appropriate, $+5$ indicated with certainty that inpatient detox was required, and 0 if they were unable to determine whether inpatient or outpatient

treatment should be offered. Additionally, they provided three reasons to support their decision for each case vignette. Based on these scores, the focus group then determined their consensus opinion as to whether inpatient or outpatient treatment was appropriate; of submitted case vignettes, 11 were rated by $\geq 60\%$ as either ≤ 3 (outpatient) or ≥ 3 (inpatient) management, 1 vignette was rated by 10 as inpatient and 1 did not comment (consensus decision was inpatient) and in eight vignettes they were unable to determine whether treatment should be inpatient or outpatient based. A further panel of 5 qualified addiction medicine specialists then reviewed responses provided around each vignette where there was consensus of $\geq 60\%$ to determine biological, psychological, and social criteria for determining whether treatment should be inpatient or outpatient based (Table 2). Additionally, the authors commented that while these criteria can be useful in assisting the setting of detoxification, it is also important to consider the patient's wishes when making the final decision.

Having made the decision to admit a patient for GHB or related analogue withdrawal, then the next considerations are (i) when to dose and (ii) what drug(s) should be used in the management of withdrawal. Unlike individuals presenting with alcohol or opioid dependency, where standardized validated scoring systems such as Clinical Institute Withdrawal Assessment for Alcohol revised tool (CIWA-Ar) and the Opioid Withdrawal Score can be used to determine when drug treatment is required, there is currently no recognized or validated scoring system for GHB or related analogue withdrawal. While some of the features of GHB or analogue withdrawal will be detected using the CIWA-Ar tool, this scoring system is only used clinically every 2 h, whereas GHB withdrawal patients can deteriorate more rapidly between these fixed scoring intervals. In addition, previous experience has shown that scoring all of the neuropsychiatric effects is not sufficient to dose patients appropriately [102, 140, 141]. In 8 patients undergoing detoxification (4 inpatient, 4 outpatient), CIWA-Ar scores were calculated during the first 24 h of withdrawal management and CIWA-Ar triggered

Table 2 Decision-making criteria for inpatient vs. outpatient detoxification treatment [139]

	Outpatient detoxification	Inpatient detoxification
Biological criteria	GHB abuse ≤ 32 g/day ≥ 2 h frequency Limited/no night use No history of severe withdrawal symptoms Limited psychoactive substance co-use	Pregnancy Severe somatic disease (e.g., hepatic, renal, or cardiovascular impairment) Epilepsy
Psychological	Psychiatric disorders mild or in stable form	Psychiatric disorders such as psychosis, bipolar disorders, severe anxiety, depression, ADHD on treatment
Social	Socially integrated Stable supporting system Residence	Social disintegration Drugs abuse in system Rambling

benzodiazepine dosing was compared to symptom triggered dosing. In the inpatient treatment group, all had episodes where the CIWA-Ar was less than 10 (no benzodiazepine dosing) but the patient required benzodiazepines based on clinical manifestations (33–100% of times where CIWA-Ar was < 10). Additionally, the opioid withdrawal scale (OWS) has been used to determine the frequency of symptoms in this scale in 15 patients with acute GHB or related analogue withdrawal [142]. While some features were present in 14 or 15 of the patients (fatigue, agitation, craving, tremors, sweating), others were less frequently present (anxiety, sleepiness, muscle twitches, pupil dilatation, running nose, looks depressed, abdominal pain, vomiting) and some were not present at all (yawning, “goose flesh,” watering of eyes, general restlessness, nausea, seizures, dullness/slowness). This suggests that currently

patients should be treated using a “symptom-triggered dosing regimen” rather than attempting to utilize a scoring system such as CIWA-Ar or OWS to determine when dosing should be administered.

The optimal management regimen for GHB, GBL, and 1,4BD withdrawal is still unclear. Some of the potential drug treatments tried and recommended are summarized below. Currently, the majority of patients are managed with benzodiazepines, either alone or in combination with other drugs. There is increasing evidence on the use of novel treatment modalities, particularly baclofen and pharmaceutical grade GHB. It is likely that over the next 5–10 years a standardized treatment regimen will become more widely available, although the legal status of certain treatments in different countries may limit the widespread use of these drugs.

Physical Restraints

Some authors have reported the use of physical restraints in managing patients with acute delirium and other neuropsychiatric effects seen in acute GHB or related analogue withdrawal [46, 94, 96, 100, 143]. However, we would not recommend their routine use due to the potential for trauma and serious physical injury to a patient in the setting of severe delirium, agitation, and/or aggression.

Benzodiazepines

To date, a substantial portion of the published literature and the first published treatment regimen has focused on the use of benzodiazepines in acute GHB and related analogue withdrawal [1, 93, 101, 102]. Benzodiazepines are used in a variety of other withdrawal scenarios (e.g., alcohol, benzodiazepines), largely due to their activity at the GABA-A receptor. Theoretically, regular use of GHB or a related analogue could lead to tonic inhibition of the glutamergic excitatory neurotransmitter system which in turn leads to upregulation of this system. During withdrawal as the inhibitory GHB is removed, it is likely that the hyper-excitability is mediated through

the *N*-methyl-D-aspartate-glutamate receptor complex, which may be insensitive to benzodiazepines. However, it is possible that benzodiazepines may have an inhibitory effect through their GABA-A activity. In addition, as discussed in the pharmacology section, GHB acts predominately through the GABA-B receptor, and therefore this in part may explain why benzodiazepines alone may be insufficient in most cases of GHB and related analogue withdrawal. In our experience, almost 50% of those patients presenting to hospitals with acute unplanned withdrawal will require additional treatments beyond just benzodiazepines and possibly admission to an Intensive Care Unit for ongoing management. Often these individuals have delirium at the time of presentation [102].

Some reports have used of different benzodiazepines (Diazepam, Clonazepam, Temazepam, Lorazepam, Chlordiazepoxide) and administration by different routes, but there are no data to suggest that any one benzodiazepine is superior to others [1, 46, 94, 96, 97, 100, 102, 103, 143]. We recommend that they be administered by the most appropriate route depending on the severity of the withdrawal and the ease of administration.

In the review of published cases of acute GHB, GBL, or 1,4-BD withdrawal, of the 57 patients identified 90% were treated with benzodiazepines and 20% received no additional treatment [93]. Similarly, in a further 38 cases of acute GHB/GBL withdrawal 91% of patients were treated with a tapering course of benzodiazepines, although in 82% this was in combination with one or more other drug treatment [101]. The overall diazepam equivalent doses of benzodiazepines required to “manage” the acute withdrawal ranged from 20 to 2,655 mg. Based on the review of these cases, the authors postulated a potential algorithm for managing acute GHB or GBL withdrawal, which was dependent on the frequency of use, total daily dose of GHB or GBL used, and the presence or absence of delirium on presentation to the healthcare facility:

- Less than 3 doses per day, <30 g GHB per day, or <15 g GBL per day then consider outpatient

treatment with 20–40 mg diazepam initially reducing over 7 days with daily physical assessments

- More than 3 doses per day, >30 g GHB, or >15 g GBL per day with no delirium on presentation then manage initially with 80–150 mg diazepam reducing over 7 days
- More than 3 doses per day, >30 g GHB, or >15 g GBL per day with delirium on presentation, treat with high-dose diazepam (150–200 mg per 24 h) and if benzodiazepine resistant after the first 24 h, add pentobarbital in an ICU setting

Interestingly, while these authors made recommendations about the ongoing management and reducing of benzodiazepine doses in the less-severe groups, there was no real recommendation on ongoing management after the first 24 h for the most severe group (heavy use with delirium present). After the initial period of assessment with benzodiazepines based on symptoms/signs of acute withdrawal, we recommend the use of a reducing regimen based on the requirements in the first 24 h; in our experience we use a regimen based on tapering with Chlordiazepoxide after the first 24 h along the same lines as that used for alcohol withdrawal. These patients may need an extended tapering course, since as noted previously the withdrawal from GHB and its analogues tends to be more prolonged compared to ethanol [102].

GHB and GBL

There has been interest in the Netherlands and Switzerland in the use of GHB and GBL in the management of withdrawal [142, 144–146]. As summarized below, while there is some evidence for the use of pharmaceutical grade GHB, one major limitation to its use in these situations in many countries is the existing controls around how it is stored, prescribed, and/or administered which will make it practically difficult to administer within most healthcare environments. In addition, the use of illicit GBL (or GHB) from street-level drug dealers is more complicated not only by its legal status but also by the

variability in the concentration of the sourced drugs.

The use of tapering doses of pharmaceutical grade GHB has been shown to be beneficial in the management of GHB withdrawal [142, 145, 146]. Twenty three patients with GHB-dependence (average duration of GHB use 1.6 years, dosing 2–4.2 g per dose every 45–90 min) were recruited to be managed with a tapering dose of GHB [142]. The initial dose of pharmaceutical grade GHB (specifically produced at a concentration of 150 mg GHB/mL) administered was approximately 60–70% of their usual dose. This was then increased or decreased by 0.45–1.2 g of GHB every 3 h based on symptoms of withdrawal or over-sedation until an “acceptable dose” was determined. From the second day, the dose of GHB administered was tapered by 0.3–0.45 g per medication dose each day. During the withdrawal period, individuals completed a Subjective Withdrawal Scale (a 35 point scale with a maximum score of 140) and using a tapering dose of GHB the SWS decreased from an initial mean of 26 (range 6.4–109.9) to 5.9 (range 0–26) on day. There were no episodes of psychosis or delirium with this treatment regimen, and all patients were managed within an addiction treatment facility. It should be noted that 16 patients experienced uncomfortable withdrawal symptoms between the 3 h doses, particularly on the first 3 days of treatment, suggesting the interval between dosing was too long. In addition, 16 patients required additional treatment with diazepam and 8 patients required treatment with temazepam for severe insomnia, suggesting that the dose of GHB administered was not sufficient to manage all of the withdrawal symptoms. As a result of these initial reports of using pharmaceutical grade GHB, there has been more widespread use of this grade of GHB in the management of GHB withdrawal in The Netherlands. In a review of 229 patients treated using this protocol, 86% of patients successfully underwent detoxification. Of the remaining patients, 8% self-aborted treatment and 6% were discharged for ongoing use of street GHB in addition to the pharmaceutical grade GHB [146]. More recently,

there have been reports of using pharmaceutical grade GHB in the management of patients with benzodiazepine-resistant GHB withdrawal [145]. Three patients (28-year-old female, 33-year-old male, 42-year-old male) with GHB-dependency all failed initial treatment with benzodiazepines and were commenced on pharmaceutical grade GHB with rapid resolution of the GHB withdrawal symptoms and stabilization of the patient. Based on the clinical experiences reported to date using pharmaceutical grade GHB, the authors suggested a modified treatment regimen using a licensed prescribable pharmaceutical grade product (Xyrem, sodium oxybate) which has a GHB concentration of 500 mg/mL (compared to the 150 mg/mL produced for the initial studies of tapering doses of GHB in the management of GHB-dependency).

There is only one case report on the use of street GBL in GBL-dependency, and no published data on the use of pharmaceutical grade GHB in patients with GBL-dependency. A 36-year-old female who had been treated on several occasions for GBL-related withdrawal with benzodiazepines, less than optimal control of her with severe behavioral disturbances, was hospitalized with a further episode of GBL withdrawal [144]. During this admission, she was noted to be attempting to self-administer GBL and was assisted in the self-administration of 2–4 mL every 5 min over a period of 30 min. Over this time, her behavioral disturbances settled, she became oriented and her cognitive function and mental capacity were restored. Unfortunately, she then left the hospital, making it not possible to determine whether continuation of the self-administered GBL could have successfully managed her withdrawal.

Baclofen

Baclofen is a GABA-B receptor agonist and since GHB acts at the GABA-B receptor, pharmacologically baclofen would be expected to have a potential role in the management of GHB and related analogue withdrawal. In animal models, cross-tolerance to baclofen has been seen in both rats and baboons chronically administered GHB [20, 43]. It is likely that baclofen, similar to methadone

in opioid withdrawal, is acting as a substitution agent rather than managing the withdrawal itself.

There are currently limited clinical data on the use of baclofen in the management of acute GHB and related analogue withdrawal [102, 107, 147, 148]. A 61-year-old female with chronic dependency on GHB (initially prescribed for insomnia, but increased doses/frequency to treat anxiety and worsening insomnia) was admitted to an ICU from a psychiatric detoxification facility following seizures during acute GHB-related withdrawal [147]. She was initially treated with GHB every 4 h (prehospital she was taking GHB every 3 h) with additional benzodiazepines but had increasing seizures and was started on 5 mg baclofen every 8 h. Her seizures ceased, and they were able to wean her GHB dosing as her baclofen dosing was increased to 10 mg every 8 h.

Following this case report, there was a case series of individuals with GBL-dependency treated with both diazepam and baclofen in an outpatient detoxification service [148]. In this case series of 19 patients, 17 were treated with baclofen (10 mg three times a day) in addition to symptom triggered diazepam on day 1 of outpatient treatment. There were no specific unwanted effects associated with the baclofen. Several patients reported that the baclofen helped to “reduce craving for GBL,” and four continued baclofen for “several weeks” afterwards, which assisted with sleep, concentration, and anxiety control. Fifteen patients remained “nondependent” at the last contact with the drug treatment service (up to 2 months following completion of the withdrawal treatment). Of the ten patients who were contacted by telephone at 2 months, eight reported that they were abstinent from GBL use and two reported that they had “dabbling” GBL use. Based on these few published cases and our previous experience, our current local policy for managing GHB/GBL withdrawal is symptom triggered benzodiazepine administration with baclofen (10 mg three times a day) on day 1, followed by a reducing course of benzodiazepines for 5–7 days; the baclofen is continued during the reducing course of benzodiazepines and then weaned over the last 24–48 h of treatment [102, 107]. There has also been interest

in “preloading” with baclofen in the 24–72 h prior to starting detoxification, in an attempt to stabilize an individual’s use of GHB or related analogue and potentially to improve the overall detoxification management. However, in our experience some individuals report that baclofen can make them feel too drowsy and/or develop other unwanted effects such as ataxia and unsteadiness. Although there is a pharmacological basis for the use of baclofen in the management of GHB withdrawal and anecdotal experiential evidence that it is beneficial, there are no proven data to support its use and/or to look at utilizing this in preference to benzodiazepines. We are involved in a randomized placebo controlled trial looking at the feasibility of using baclofen during both preloading and treatment of GHB and related analogue withdrawal in both inpatient and outpatient setting.

Treatment with baclofen, along with other drugs, has typically been during the acute withdrawal phase, with drugs being tapered or ceased after a short period of time. However, the first reported case of baclofen use in GHB withdrawal was followed by 10 weeks of baclofen at 10 mg three times a day. During this time the individual was reported to be abstinent from GHB [147]. There is increasing interest in the potential for using a more prolonged course of baclofen to prevent relapse of GHB use following initial detoxification [149, 150]. Fourteen patients with a history of GHB dependency were recruited to undergo detoxification with GHB followed by a maintenance course of GHB for 12 weeks following stabilization of dose [149]. Patients were initially treated with 5 mg baclofen three times a day, along with a maximum of 20 mg diazepam a day, and the baclofen dose was increased by 15 mg every 3 days until a maintenance dose of baclofen was achieved in the second week of treatment. This was continued for a further 12 weeks before tapering over a further 2 weeks. During the maintenance period, abstinence from GHB use and impact on cravings were assessed. It should be noted that three patients were excluded from the trial due to severe psychiatric symptoms [2] or drop-out [1], suggestive that this initial baclofen-only based treatment regimen would only be suitable for those who do not develop severe

withdrawal symptoms (i.e., less useful in the intensive care setting). Five individuals remained abstinent throughout the study (one additional patient was abstinent for 7 weeks and then dropped out of the study), while four used on one or more occasion during the study and one relapsed to regular GHB use after 5 weeks of treatment. Overall, prolonged use of baclofen appeared to reduce cravings for GHB, with only one patient reporting that there was no change in their craving for GHB. The most common unwanted effects were dry mouth (seven patients, reported as present frequently), sweating/tremors/fatigue (five patients, reported as present sometimes), and drowsiness/sedation (four patients, reported as present sometimes); three patients reported no unwanted effects with the baclofen treatment. Based on the experience in this small case series, there is currently an open label study of baclofen for relapse prevention in the management of GHB dependency underway [150]. In this study, 40 patients are being recruited to receive baclofen (45–60 mg per day) following detoxification, and its impact on relapse to GHB use within 6 months of recruitment (primary outcome measure), craving for GHB, psychiatric symptoms, and quality of life, will be compared with a treatment as usual cohort (40 patients) and historical controls (274 patients).

The unwanted effects of baclofen are predominantly neuropsychiatric (for example, sedation, drowsiness, confusion, euphoria or depression, visual disturbances, ataxia, tremor, nystagmus, hallucinations, nightmares, dizziness, insomnia); other unwanted effects include gastrointestinal upset, hypotension, dysuria and urinary frequency, abnormal liver function tests, and hyperhidrosis. These unwanted effects are more common at the start of treatment and particularly if the dose is escalated too quickly; they are typically transient and can be treated by appropriate dose-reduction. There has been a report of severe acute toxicity related to co-use of GHB in an individual being treated with baclofen for GHB detoxification [151]. The 21-year-old female patient completed her fourth GHB detoxification program and was commenced on baclofen for relapse prevention. She was found unconscious

with bradypnoea and episodes of respiratory apnoea and a bottle of GHB in her pocket. Following supportive care, she recovered and subsequently reported that she had relapsed into regular GHB use, which had been without problems until she co-used 80 mg of baclofen concurrently. It is therefore important that if considering outpatient unsupervised use of baclofen, either during acute withdrawal or as part of relapse prevention, that patients are appropriately counseled about the potential risks of severe acute toxicity if baclofen is co-used with GHB or a related analogue.

Other Drugs

A range of other drugs have been reported to be used in patients either alone or in combination with benzodiazepines. These include antipsychotics (haloperidol, trifluoperazine, risperidone, trazadone, quetiapine), barbiturates (pentobarbital), and other sedatives (clonidine, propofol, diphenhydramine, chloral hydrate) [1, 46, 91, 93, 95, 96, 101, 105, 152]. In the series of 38 cases of acute GHB/GBL withdrawal, the frequency of other used pharmacological treatments was: antipsychotics – 43%; anticonvulsants (valproate, carbamazepine, gabapentin) – 21%; barbiturates – 18%; chloral hydrate – 8%; trazadone – 8%; baclofen – 5%; clonidine 5%; beta-blockers – 5%; propofol – 3%; and bromocriptine – 3% [101]. There was a similar frequency of other drugs used in the 57 cases of acute GHB or related analogue identified in the literature review: antipsychotics – 63%; anticonvulsants – 23%; barbiturates – 18%; chloral hydrate – 8%; trazadone – 5%; baclofen – 10%; clonidine – 13%; beta-blockers – 8%; propofol – 8%; bromocriptine – 3%; fentanyl – 3%; and physostigmine – 3% [93]. Despite the frequent use of antipsychotics in these cases, there is concern with using antipsychotics in the setting of acute GHB or related analogue withdrawal as they can potentially both lower the seizure threshold and lead to prolongation of QT/QTc with associated increased risk of arrhythmias. The increased risk of seizures when using antipsychotics has been reported in the setting of acute alcohol withdrawal [153]. In addition, there is a

report of an individual who allegedly developed “neuroleptic malignant syndrome” while being treated with haloperidol, loxapine, and benzodiazepines for GBL withdrawal [154].

In terms of barbiturates, there is a pharmacological basis for using pentobarbital over other barbiturates. Unlike most other barbiturates, Pentobarbital is able to directly open GABA-A related chloride channels and voltage-gated chloride channels [123]. Therefore, there is the potential that pentobarbital may be more beneficial in patients with severe withdrawal unresponsive to benzodiazepines. There has been a case series of four individuals with severe GBL withdrawal, where pentobarbital was used [143]. Two patients received pentobarbital after treatment failure with 6 h of high-dose lorazepam and the other two received it at the onset of treatment. All had rapid (reported as within 2–6 h) improvement in their symptoms after pentobarbital [1–2 mg/kg every 30–60 min]. Subsequent weaning of the pentobarbital resulted in a recurrence of the withdrawal symptoms. All four patients were managed without the need for intubation and mechanical ventilation as there was no associated respiratory depression and there was no hypotension seen with some other sedatives.

Criteria for ICU Admission	
Acute toxicity	Prolonged reduced level of consciousness not improving after 2–3 h of onset
	Vomiting and risk of aspiration requiring endotracheal intubation for airway protection
	Prolonged and/or recurrent seizures
	Acute toxicity from co-ingestants that requires admission to ICU
Withdrawal cases	Patients with agitation/aggression not manageable in a general ward area
	Requirement for intravenous benzodiazepine treatment if not available in a general ward area
	Requirement for IV barbiturates and/or other sedative treatment where intubation and ventilation is indicated

Special Populations

In addition to the risk of acute toxicity due to accidental or intentional ingestion of GHB or its analogues, there was previously an issue of acute 1,4-butanediol toxicity in children due to the inappropriate use of the solvent in the production of toy bead products (known as Aqua Dots in North America and as Bindeez Beads in Europe and Australia) [155–157]. In 2008, there were reports from Emergency Departments in the UK, Australia, and North America of young children presenting with significantly reduced levels of consciousness and in some instances nonresponsive coma, with rapid recovery and no long-term neurological sequelae. Although the clinical picture was in keeping with acute GHB or analogue toxicity, there appeared to be no obvious source of exposure. This clinical suspicion of acute GHB-like toxicity was confirmed when GHB was detected on toxicological testing. Through further questioning of the child, parents, and/or siblings, the common feature between these cases was that the affected child had been playing with a toy bead product prior to becoming affected. The product labeling did not mention that the beads contained GHB or any of its related analogues. However, they reportedly contained an alternative solvent known as 1,5-pentenediol (1,5-PD). Toxicological analysis of the both Aqua Dots and Bindeez Beads demonstrated that they did not contain 1,5-PD but instead contained 1,4-BD. It has been reported that the manufacturers in China intentionally changed from using 1,5-PD in the production to 1,4-BD. It is not clear whether they were aware of the potential toxicity of the alternative solvent used. The reasons for this change in solvent are unclear. It is possible that this occurred due to the cheaper cost of 1,4-BD compared to 1,5-PD or that the production processes are easier if 1,4-BD is used. Following the discovery that these products contained a GHB analogue, there was an international recall of this product to prevent further cases of accidental 1,4-BD.

The hallucinogenic indolealkylamines (IAAs) are analogues of 5-hydroxytryptamine (5-HT or serotonin), a monoamine neurotransmitter known to influence human mood and behaviors. IAAs include many natural substances and are listed in Table 1. Indolealkylamines have been used in ritual for centuries. Ceremonial use of hallucinogenic mushrooms by native populations was documented in the 1500s after the Spanish conquest of Mexico [1]. Evidence suggests that bufotenine (5-hydroxydimethyltryptamine) is not psychoactive in vivo due to its poor penetration of the blood–brain barrier [2–4]. *N,N*-Dimethyltryptamine (DMT) is a naturally occurring tryptamine found in mammalian brain. In South America, it is used in snuff for religious ceremonies [5]. Methylated indolealkylamines, derived from 5-HT via methylation [6–9], are endogenous in humans including 5-MeO-DMT found in the pineal gland and retina.

Indolealkylamines have also been isolated or synthesized for use in the treatment of migraine headaches including ergotamine and triptan drugs (sumatriptan, naratriptan, and almotriptan). Because of their similarity of structure, the synthetic hallucinogens lysergic acid diethylamide (LSD), dipropyltryptamine, α -methyltryptamine (AMT), diethyltryptamine (DET), 6-hydroxydimethyltryptamine, α -ethyltryptamine (ET), and 4-acetoxy-*N,N*-dimethyltryptamine (*o*-acetylpsilocin) are considered to belong to this group. LSD is an ergot derivative and an especially potent hallucinogen that has had an enormous cultural impact since its discovery by the Swiss chemist Hofmann in

Table 1 Indolealkylamine Sources

Chemical group	Name	Source
Tryptamines	Psilocin	<i>Psilocybe</i> mushrooms
	Psilocybin	African shrub <i>Tabernanthe iboga</i>
	Ibogaine	Sonoran Desert toad <i>Bufo alvarius</i>
	Bufotenine	Sonoran Desert toad <i>Bufo alvarius</i> and
	5-methoxy- <i>N,N</i> -dimethyltryptamine (5-MeO-DMT)	Numerous plant preparations including <i>Virola</i> snuffs
β-carbolines	Harmine	South American plants <i>Peganum harmala</i> and <i>Banisteriopsis caapi</i>
	Harmaline	Drought-tolerant perennial plant, <i>Peganum harmala</i> and ayahuasca; hallucinogenic brew made from the South American jungle vine, <i>Banisteriopsis caapi</i>
Ergolines	Lysergic acid amide	American tropical morning glory species <i>Ipomoea violacea</i> and
	Isolysergic acid amide	<i>Rivea corymbosa</i>

1938 [10]. Additionally, it has provided insight into the chemical and molecular bases of human psychosis.

Indolealkylamines of fungal origin such as psilocin, ibotenic acid, and muscimol have been proposed for use in psychiatry and psychotherapy inciting controversy. Some recent findings suggest these compounds can improve perception and mental skills. The states of altered consciousness elicited using psychedelic drugs in religious settings increase susceptibility to suggested messages and can be accompanied by negative emotions such as fear, terror, anxiety, shame, or sense of guilt. Induced psychotic episodes may result in psychopathology including confusional syndrome and schizophrenia [11–17].

Psilocybin/psilocin is presently used to model schizophrenia and study psychosis [18–27].

Hallucinogenic compounds from fungi of the genera *Psilocybe* and *Amanita* have been used recreationally since the early 1960s [28, 29]. Psilocin and psilocybin, the psychoactive principles of *Psilocybe* mushrooms, were isolated and identified by Hofmann in 1958 [30]. Ibotenic acid and muscimol seemed the most active hallucinogens from fly agaric [31–33]. Chronic exposure to these substances is associated with mental health disorders as well as cardiovascular and neurodegenerative complications.

Given adverse effects, including fear, anxiety, paranoia, personality change, and psychosis, most claims of therapeutic benefit from psilocybin or

psilocin in psychotherapy are on tenuous footing at best. Benefit has been observed, however, in the treatment of obsessive-compulsive disorder [34–38]. A therapeutic benefit in treating cluster headaches has also been reported [39]. In order to limit abuse of indolealkylamine hallucinogens, many of them have been added to the US Drug Enforcement Administration's (DEA) list of controlled substances. ET, AMT, bufotenine, DET, DMT, ibogaine, LSD, psilocybin, and psilocin are all DEA Schedule I, defined as substances with no currently accepted medical use and a high potential for abuse. Lysergic acid and lysergic acid amide (LSD precursors) are Schedule III, defined as having low to moderate potential for physical or psychological dependence.

Severe toxicity from indolealkylamine hallucinogens is uncommon, although abuse of these agents is prevalent. The exact prevalence of use is impossible to determine because of the inherent inaccuracies of self-reporting, the substitution of one substance for another by dealers, and the lack of laboratory confirmation in most cases. In one survey of 1500 American college students, 15% admitted to mushroom abuse and 5% admitted to misuse of LSD [40]. The 2014 American Association of Poison Control Center's National Poisoning Data System (NPDS) report documents 520 single exposures and one death from LSD and 335 single exposures to hallucinogenic mushrooms containing psilocybin and psilocin and no deaths [41].

Fig. 1 Chemical structures of common hallucinogenic agents. The tryptamines are structurally similar to serotonin

Death from poisoning by these substances is rare and often related to secondary events, such as trauma while intoxicated. Many toxic sequelae of poisoning with the indole hallucinogens are potentially life threatening, however, and could result in the necessity of intensive care unit admission.

Biochemistry and Clinical Pharmacology

The three main chemical groups of hallucinogens of clinical importance are the indolealkylamines (the subject of this chapter), phenylethylamines, and atypicals (arylcyclohexylamines).

Representative chemical structures of indolealkylamines are illustrated in Fig. 1. There is substantial chemical similarity between the indolealkylamine hallucinogens and the neurotransmitter serotonin (5-hydroxytryptamine [5-HT]). Although there is variety in structure among hallucinogens, which may account for differences in their clinical presentation overall, agonism at select cerebral serotonin receptors seems to be a necessary common denominator for their ability to produce hallucinations [42–44]. The commonly encountered indolealkylamines are psilocin (dimethyl-4-hydroxytryptamine); psilocybin, harmine, and ibogaine (all dimethyl-4-phosphoryltryptamine); 5-methoxydimethyltryptamine; LSD; lysergic

acid amide; isolysergic acid amide; dimethyltryptamine; dipropyltryptamine; α -methyltryptamine; diethyltryptamine; and 6-hydroxymethyltryptamine. In addition, IAAs have been developed for use in migraine therapy [45–47]. Ergotamine acts mainly via 5-HT_{1B/1D} receptors. The side effects are mediated via dopamine and 5-HT_{1A} receptors. Newer triptans are much more selective for 5-HT_{1B} and 5-HT_{1D} receptors with high affinity [48].

Tryptamine (see Fig. 1) serves as the basic structural unit for serotonin and the indolealkylamine hallucinogens. The IAAs are made up of an indole moiety and a basic nitrogen atom connected by an alkyl chain of at least two carbons in length [48]. Dialkyltryptamines, such as dimethyltryptamine, diethyltryptamine, and 5-methoxydimethyltryptamine, are not psychoactive if given orally, presumably due to rapid hepatic metabolism, and generally are smoked or, in native cultures, inhaled as snuff [49]. Exceptions to this lack of oral activity are psilocin and psilocybin. The latter is converted by hydrolysis in vivo to the former, which is the active species [50, 51]. Affinity of indolealkylamines for 5-HT₂ receptors seems to be influenced by the lipophilicity and electron-withdrawing properties of the four-position substituents [52]. The mechanism of hallucinogenesis seems to be sensitive to ring substitution. With the exception of 5-methoxy, 4-methoxy, or 4-phosphoryloxy (psilocybin) substituents, no other ring-substituted compounds have been found to be psychoactive in humans [49].

Structural features on the aliphatic side chains also influence activity. An α -methyl group confers the ability to resist degradation by monoamine oxidase and to be orally bioavailable.

α -Methyltryptamine is not degraded by monoamine oxidase, preventing the metabolism that so rapidly occurs with other non- α -methylated tryptamine derivatives. The α -methylated compounds, such as α -methyltryptamine, have an increased duration of action [53]. Stereochemical considerations also are important. With α -methyltryptamine and 5-methoxy- α -methyltryptamine, the (+) enantiomer is the most active [54, 55].

Radioligand competition studies in rats revealed the following structure-activity

relationships for IAAs at serotonin receptors: All IAAs show greatest potency for the 5-HT_{2A} receptor; most show 2–10 times lower affinity at 5-HT_{2B} receptors; moieties lacking indole ring substitutions at the 4- or 5-position showed lower affinity for all 5-HT receptors; 4-hydroxylated derivatives had 25–380-fold selectivity for the 5-HT_{2A} versus 5-HT_{1A} receptor; 5-substituted derivatives were equally potent at both 5-HT_{1A} and 5-HT_{2A} receptors; 6-substituted derivatives showed > micromolar affinities for all 5-HT receptors studied; the *N,N*-dialkyl substituent was a secondary determinant of affinity, i.e., substituents larger than *N,N*-diisopropyl markedly reduced affinity at 5-HT_{2A} and 5-HT_{1A} receptors; and hallucinogenic 4-hydroxy-indolealkylamines, like the psychotomimetic phenylisopropylamines, are potent and selective ligands at 5-HT_{1A} receptors [56].

LSD is extensively metabolized in animals [48]. At least 4 urinary metabolites have been identified in humans [57]. The metabolism of psilocybin and psilocin is not well characterized at this time. Psilocybin is a secondary metabolite of mushrooms of the following genera: *Agrocybe*, *Conocybe*, *Copelandia*, *Galerina*, *Gymnopilus*, *Hypholoma*, *Inocybe*, *Panaeolina*, *Panaeolus*, *Pholiotina*, *Pluteus*, and *Psilocybe*. Most mushrooms are cultivated – *Psilocybe cubensis* is the mushroom of choice for abusers, is easy to culture, and fruits readily in vitro. Oral psilocybin is quickly hydrolyzed in the gastrointestinal tract. Phosphorylation in the stomach or via alkaline phosphatase in the small intestine produces psilocin, the active form of the drug, which unlike psilocybin is easily absorbed from the GI tract. There is glucuronidation of psilocin metabolites in the liver and intestinal tissue [58]. Ibogaine is a Schedule I substance which undergoes *O*-demethylation by CYP2D6 as a dominant pathway to an active metabolite, noribogaine. As a result, ibogaine has potential for significant drug–drug interactions in co-ingestion with CYP2D6 inhibitors such as the serotonin-selective reuptake inhibitors paroxetine or fluoxetine or the antiarrhythmic drug quinidine [48].

The tryptamines, including DMT, bufotenine, and 5-MeO-DMT, are primarily excreted via

oxidative deamination involving monoamine oxidase A (MAO-A) [59–63]. Oral DMT undergoes extensive first-pass metabolism via the monoamine oxidase (MAO) system necessitating co-ingestion of an MAO inhibitor-containing plant (e.g., *Banisteriopsis caapi*, in ayahuasca brews) in order to achieve a psychedelic response [64]. Alternatively, smoking a plant mixture extract can bypass hepatic first-pass metabolism to allow the parent compound to gain access to the CNS [65].

5-methoxy-*N,N*-dimethyltryptamine is mainly deactivated via deamination by MAO-A. A secondary metabolic pathway involves *O*-demethylation by CYP2D6 to the active metabolite, bufotenine [66, 67], which binds to the 5-HT_{2A} receptor with an affinity ten times that of the parent compound [68, 69]. However, its psychedelic potency has been questioned due to its poor lipid solubility and penetrance of the blood–brain barrier (BBB) [70–72]. 5-MeO-DMT showed nonlinear pharmacokinetics in mice suggesting saturable hepatic metabolism [73]. Bufotenine is Schedule I, while 5-MeO-DMT is not.

MAO inhibitors lengthen the elimination of 5-MeO-DMT and increase production of bufotenine. Defective allelic isoforms of CYP2D6 were associated with decreased production of bufotenine [74]. The main pathway of bufotenine metabolism is also deamination via MAO so an MAO inhibitor also inhibits its elimination. Thus, the C_{\max} and AUC of bufotenine are increased 2.6- and sixfold, respectively, in mice after harmaline pretreatment [74].

Little is known about the metabolism of many of the β -carbolines. Metabolism of the β -carbolines by *N*-methyltransferase can produce highly neurotoxic metabolites [75, 76]. Harmaline is metabolized by CYP2D6, which is known to be subject to genetic polymorphisms [77]. Prolonged exposure to harmaline can result following ingestion in patients who are poor metabolizers [78].

5-MeO-DMT, harmaline, and bufotenine are all serotonergic agonists and may in combination produce a serotonin syndrome. 5-MeO-DMT is also a serotonin reuptake inhibitor [69]. Additionally, harmaline, as an MAOI, inhibits 5-HT

metabolism as well as that of 5-MeO-DMT. The result is increased and prolonged exposure to the latter as well as shunting metabolism to *O*-demethylation increasing production of the psychoactive metabolite, bufotenine [48]. In this light, it is not surprising that co-ingestion of 5-MeO-DMT and harmaline is associated with fatalities [79, 80]. Harmine has two primary oxidative pathways of metabolism, *O*-demethylation, and 6-hydroxylation. The former is catalyzed by CYP2D6, 1A1, 1A2, 2C9, and 2C19 [81]. A human study identified fast and slow metabolic phenotypes for harmine as well, suggesting CYP2D6 polymorphism may be a significant factor in its clinical presentation [82].

Ibotenic acid and muscimol are the major active constituents of *Amanita muscaria* and *A. pantherina*, products of fungal secondary metabolism. Their endogenous analogues are glutamic acid and gamma-aminobutyric acid (GABA). The minimal psychedelic dose for muscimol is 6 mg, 30–60 mg for ibotenic acid [58]. Muscimol, unlike GABA, is able to cross the BBB, possibly via active transport [83–85]. GABA-gamma-oxoglutarate transaminase appears to be involved in the rapid conversion of muscimol to metabolites [86]. One metabolite, tricholomic acid, has been shown to be active in inhibiting neurons [87, 88]. Ibotenic acid is metabolized in vivo to muscimol [89]. Both are renally excreted and have been detected in human urine 3–8 h after ingestion [90].

Pharmacokinetics of Indole Hallucinogens Lysergic acid diethylamide (LSD)

Volume of distribution: 0.27 L/kg after 2 μ g/kg intravenously, elimination half-life calculated at 103 min, hepatic elimination via hydroxylation, glucuronidation, and excretion in bile, small amounts excreted unchanged in urine [91]

Absorption: well absorbed via gastrointestinal tract

Peak levels: 30–60 min after 2 μ g/kg orally, reduced slightly and delayed by food [92]

Plasma protein binding: >80%

(continued)

Elimination half-life: approximately 2.5 h, approximately 0.01% crosses blood–brain barrier [93]

Psilocybin

Duration of action: briefer than LSD's, usually approximately 4 h [94] (6–12 h for LSD)

Bioavailability (of psilocin after oral psilocybin): 50%

Peak levels: 50–100 min, slowly decreases after 5–6 h

Elimination: 65% excreted in the urine, 15–20% in bile and feces within 8 h from ingestion [58]. 10–20% remains longer (psilocin has been detected in urine 7 days after oral psilocybin administration) [95]

Dimethyltryptamine

Intense and shorter trip than LSD, lasting 30–60 min

Smoked, snorted, or injected [94]

Smoking DMT produces symptoms within one minute and peak effect in 2–5 min. The duration of action is 20–60 min [65]. *Mechanism of clearance:* dimethyltryptamine and 5-MeO-DMT eliminated:^[96] (1) via monoamine oxidase by oxidative deamination (major route of metabolism in brain, liver, and kidney), (2) by *N*-oxidation (major metabolic route in peripheral tissues [e.g., liver and kidney], minor in brain), and (3) only 8% of administered dose of either recovered as metabolites in urine

Bufotenines

(5-methoxydimethyltryptamine)

Single deep inhalations of vaporized venom is powerfully psychoactive within 15 s [96]

5-HT_{2C} receptor acts as a modulator [43, 44, 69, 98]. Risperidone, a potent 5-HT₂ receptor and dopamine-D₂ antagonist, completely blocks the discriminative stimulus properties of LSD in rats [99]. Antagonism of LSD's behavioral effects by 5-HT₂ antagonists, without change in the typical LSD-induced suppression of serotonin neuronal activity, suggests that these effects are mediated postsynaptically [100]. That 5-HT₂ agonism is the primary mode of action of LSD's behavioral effects is not firmly established, however. There is some evidence against a mechanism of direct pure 5-HT₂ agonism. LSD does not stimulate 5-HT₂-mediated phosphatidylinositol turnover in rat cortex, yet it inhibits serotonin's ability to produce these effects [101]. A study in monkeys found indolealkylamine administration to be transiently reinforcing in only 1 of 4 animals, suggesting that this class of hallucinogen has either weakly reinforcing effects or mixed reinforcing and aversive effects [102].

Psilocybin acts as a prodrug. Its dephosphorylation results in psilocin which is lipophilic and easily crosses the BBB. Psilocin's psychotic effects are thought to be mediated by 5-HT_{2A} receptors [103] and are blocked by the 5-HT_{2A} antagonist ketanserin in human subjects [24, 104]. Other effects on cognition and attention are not fully diminished and may even intensify when psilocybin and ketanserin are coadministered [18, 105]. It is felt that the psychotic effects result from both 5-HT_{2A} cortical stimulation and 5-HT_{1A} inhibition in the dorsal raphe nuclei, resulting in decreased serotonin release in the prefrontal cortex. Binding studies have shown that psilocin binds 5-HT_{2A} and 5-HT_{2C} receptors with high affinity and 5-HT_{1A} receptors with lower affinity [56, 103]. 5-HT_{2A} receptors are expressed by excitatory glutaminergic pyramidal neurons, but psychoactivity is felt overall to result from inhibitory influence via 5-HT_{2A} receptors on GABAergic interneurons [106]. Monoamine oxidase inhibitors are taken by psilocin users to intensify the induced hallucinations. MAO catalyzes serotonin degradation in the synaptic cleft. Psilocin, as an MAO substrate, is also an MAO inhibitor with respect to other MAO substrates such as serotonin resulting in increased levels of the latter [58].

Pathophysiology of Toxic Effects

At least three different pharmacological mechanisms of hallucinogenesis are believed to exist: dopamine D₂ receptor activation, 5-HT_{2A} receptor activation, and glutamate *N*-methyl-D-aspartic acid (NMDA) receptor inhibition [97]. Indolealkylamines and phenylethylamines produce hallucinations primarily via stimulation of the 5-HT_{2A} receptor, while the

In contrast to other IAAs, the effects of 5-MeO-DMT are mediated primarily by the 5-HT_{1A} receptor [107–110], though 5-HT_{2A} effects may be contributory as well [109], particularly with respect to the induction of hyperthermia in high doses [111]. 5-MeO-DMT is also a serotonin reuptake inhibitor.

5-Methoxy-*N,N*-dimethyltryptamine and the MAOI inhibitor harmaline are both serotonin analogues and are often abused together. Adding harmaline increases and prolongs the duration of action of 5-MeO-DMT. In a mouse study, harmaline was shown to decrease body temperature in low dose and cause hyperthermia in higher dose. Coadministration of harmaline dramatically potentiated 5-MeO-DMT-induced hyperthermia. Harmaline-induced hypothermia was only attenuated by 5-HT_{1A} antagonist administration, while hyperthermia induced by harmaline and 5-MeO-DMT was attenuated by coadministration of a 5-HT_{1A} or 5-HT_{2A} antagonist. Stress-induced hyperthermia was not attenuated by 5-HT_{1A} antagonism. The results suggest the synergistic hyperthermic response to harmaline and 5-MeO-DMT involves activation of both 5-HT_{1A} and 5-HT_{2A} receptors [112].

More recent work with receptor subpopulations has determined that LSD and the phenylethylamine DOI (1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane) serve as potent partial agonists for cortical 5-HT_{2A} receptors, inhibiting pyramidal cells in layer II, via stimulation of GABAergic interneurons in layer III, of the rat piriform cortex [113]. Indole hallucinogens initiate a 5-HT_{2A} receptor-mediated enhancement of nonsynchronous, late components of glutaminergic excitatory postsynaptic potentials in layer V pyramidal cells, which may help explain the changes in higher level cognition, perception, and mood experienced from these drugs [114].

DMT is a postsynaptic 5-HT_{2A} agonist and a 5-HT_{2C} partial agonist. The latter receptor shows a deep desensitization to DMT over time. This direct agonism decreases the rate of serotonin synthesis and turnover in the brain [115] which could account for the psychodysleptic effects of DMT [116]. DMT remaining in the brain 48 h after injection is concentrated in the olfactory

bulb. The long-term persistence of DMT in the brain is postulated to result from uptake by serotonin transporter and storage in vesicles preventing degradation by MAO. DMT has three putative receptor targets – 5-HT₂ (5-HT_{2A} and 5-HT_{2C}), trace amine-associated receptors, and sigma σ -1R receptors [117].

Muscimol is a GABA_A agonist and partial GABA_C agonist [58]. It binds to high-affinity and low-affinity sites on GABA_A receptors and functionally activates them [118]. Muscimol via GABA_A binding in cerebral cortex and hippocampus induces sedation and ataxia in mice. Muscimol inhibits GABA neuronal uptake and is a substrate for GABA's metabolic enzyme, GABA transaminase [86, 119–121]. Ibotenic acid is an NMDA receptor agonist resulting in its observed neurotoxicity [122]. High-dose muscimol potentiates psychosis in schizophrenics [123]. Muscimol causes increase in brain serotonin and decreased catecholamine levels [124] in mice and rats and decreases striatal GABA_A release in rats [125]. Muscimol when given alone decreases motor activity and when given in combination with cocaine prevents the motor hyperactivity caused by the latter which is known to depend on dopaminergic neurotransmission. It is thought that muscimol modulates dopamine release [126]. Ibotenic acid excites spinal interneurons and Renshaw cells in cats. Its excitatory activity is eight times greater than glutamate. After recovery from excitability in the case of the former, the neurons become refractory to excitation, an effect felt to be due to metabolism of ibotenic acid to muscimol [89].

Muscimol possesses analgesic properties owing to its inhibitory influence. Muscimol potentiates morphine in rats and mice [127, 128]. It also potentiates the anesthetic effects of propofol [129]. Muscimol blocks or delays drug-induced convulsions in animals [130–132]. It has been shown to improve tardive dyskinesia in schizophrenics [133, 134]. It is able to prevent cell death in ischemia–reperfusion conditions where glutamate in high dose shows toxicity [135, 136].

It is clear in any case that the effects of the indolealkylamines are much more complex than can be explained by interaction with one receptor

or binding site. LSD and dimethyltryptamine have been found to have high affinity for the DOB (a phenylalkylamine, 1-(2,5-dimethoxy-4-bromophenyl)-2-aminopropane) binding site and 5-HT_{1A} and 5-HT_{1D} receptors in addition to 5-HT₂ receptors. This high affinity for the DOB site may be crucial to the ability to produce hallucinations. It is believed that the DOB binding site represents 5-HT₂ receptors when they are in an agonist high-affinity state. The high affinity of indolealkylamines and other hallucinogens for this site may explain why they are hallucinogenic, whereas serotonin itself is not because the latter does not have high affinity for this site [52]. LSD is a potent partial agonist for 5-HT_{2A} and a partial agonist for 5-HT_{2C} receptors [137]. LSD also displays high affinity for α_2 -adrenergic receptors and submicromolar affinity for α_1 -adrenergic and β -adrenergic receptors [101]. It also has been suggested that hallucinogens are partial agonists at 5-HT₂ receptors because they occasionally seem to act as antagonists [138].

Given their status as serotonergic agonists, the indolealkylamine hallucinogens have the potential to produce a serotonin syndrome. A report of eight patients with massive LSD overdose noted many clinical findings suggestive of serotonin syndrome [139]. Interaction also has been noted between serotonergic and dopaminergic agonists with respect to hyperthermia [140]. Drug-induced hyperthermia is antagonized by serotonin receptor antagonists [141]. Psychoactive agents with dopaminergic effects, such as 3,4-methylenedioxymethamphetamine, are noted to be more potent in producing hyperthermia [142].

A case report described what the authors called neuroleptic malignant syndrome after consumption of ethanol and LSD. This case had clinical features similar to those of serotonin syndrome [143]. It was the opinion of the authors of that report that the central nervous system effects of LSD resulted in continuous muscle contraction and hyperthermia, producing muscle damage and its sequelae. Clinical effects from the indolealkylamines are attributed primarily to their effects on serotonergic neurotransmission and the sympathetic nervous system.

Clinical Presentation and Life-Threatening Complications

Many life-threatening complications are possible with poisoning from indolealkylamine hallucinogens. Most commonly, trauma or self-harm may occur secondary to the mental and behavioral changes associated with the hallucinatory state and accompanying panic reactions or paranoia. Patients for whom little or no history is available should be assumed to have associated trauma until proven otherwise. Serotonergic excess may result in life-threatening serotonin syndrome, characterized by hyperthermia, muscle rigidity, and rhabdomyolysis leading to myoglobinuric renal failure, hepatic necrosis, and disseminated intravascular coagulation. Elevation of blood pressure is common from these agents, and hypertensive crisis is theoretically possible, although it has not been reported.

LSD

True hallucinations are marked by changes in perception without significant impairment of intellect or memory. Usual doses of hallucinogens typically are not associated with alterations in consciousness or excessive stimulation at these doses. To the extent that they do occur, autonomic side effects tend to be mild and not disturbing to the patient. Addictive craving is minimal [144]. Colorful and luminous pattern hallucinations are characteristic of IAA intoxication [71]. Distortion of time perception occurs as well [48].

Typical presentations for acute LSD toxicity include psychiatric and constitutional effects. Psychiatric manifestations include acute hyperanxiety, paranoia, panic reactions, dangerous or self-destructive behavior, hallucinations, sensory distortions (e.g., misperception of shape or color), and major depressive or dysphoric reactions [145]. Constitutional signs and symptoms include nausea, diaphoresis, mydriasis, severe headache, muscle weakness, fatigue, and impaired concentration. Cases of severe toxicity also have presented with coma, hyperactivity, seizures, marked visual and auditory hallucinations,

respiratory depression requiring intubation, sinus tachycardia, fixed and dilated pupils, vomiting, vasodilation, and coagulopathy [139]. A single patient was documented as presenting unconscious with severe extrapyramidal rigidity and hyperthermia [143].

Hallucinogenic Mushrooms

Ingestion of hallucinogenic mushrooms containing psilocin or psilocybin results in perceptual distortions or hallucinations, dysphoria, mydriasis, dry mouth, hyperreflexia, tachycardia, drowsiness, euphoria, nausea, cramping, abdominal pain, and distortions of body image [146, 147]. One fatal case of mushroom poisoning was reported in a 6-year-old child who ingested *Psilocybe baeocystis* and developed hyperthermia and status epilepticus [148]. Psilocybin/psilocin intoxication results in dose-dependent increases in pulse and blood pressure [149–155] which are maximal 1–2 h after administration [152]. These clinical effects are dose dependent: 8–10 mg (0.1–0.2 mg/kg) of oral psilocybin causes only physiologic mydriasis, rarely nausea and vomiting, slight increases in pulse and blood pressure, and paresthesias [149, 150, 152–155]. Higher doses (10–20 mg in a 70 kg adult) elevate the plasma concentration 5–12 ng/mL, and psychotic symptoms begin when the plasma concentration reaches 4–6 ng/mL [156]. The induced psychosis intensifies over 30–60 min and declines after 2–3 h [27, 149, 152, 153, 156]. It is estimated that 2 g of *Psilocybe semilanceata* mushroom fruit bodies (equivalent to about 10–20 mg of psilocybin) results in mild psychosis usually experienced as pleasurable (“good trip”). Increasing the dose to 12 g (equivalent to 60–120 mg of psilocybin) typically produces a negative experience (“bad trip”). The psychosis abates after 5–6 h. The psychotic symptoms include disturbances of visual perception (illusions, hypnagogic experiences), alteration of time, color and motion perception (e.g., kaleidoscope vision), synesthesias, derealization and depersonalization, euphoria sometimes changing

to drowsiness, anxiety, mood changes, dysphoria, or extreme fear [23, 25, 104, 150, 153, 157–160]. Body image perception is distorted with sensation of swelling and numbness reported [161]. Psilocybin impairs cognition, decreasing reaction times, impairing focus and attention by eliciting strong and unusual emotions and visual stimuli, and disturbing thinking by distortion of ego and delusions [18–27, 104, 105]. Psilocybin, like schizophrenia, impairs the ability to use contextual information [22]. At high doses, the psychotic manifestations, called the schizophrenic phase, give way to a panic attack-like phase characterized by dysphoria, paranoia, and a loss of ego control perceived as negative [149, 161, 162]. Accidental death from jumping out a window has been reported after ingestion of “magic mushrooms” [163, 164]. Recurrence of induced psychotic symptoms after even a single psilocybin ingestion (aka “flashbacks”) can occur especially under the influence of other toxicants such as alcohol or marijuana [153, 164, 165].

Psilocybin is a low potency toxicant with an LD₅₀ in mice of 285 mg/kg and in rats of 280 mg/kg [166]. It may transiently elevate hepatic transaminases [152]. Psychotomimetic doses in humans (30 mg orally in a 70 kg adult) produce only slight, transient elevations in pulse and blood pressure [149, 150, 152, 154]. Blood clotting disturbances have been reported [167]. Single cases of cardiac disturbances such as supraventricular tachycardia, myocardial infarction, and takotsubo cardiomyopathy have been reported [168, 169]. Serotonergic vasoconstriction can contribute to venous ulcers and delay in wound healing, headaches, and increased risk of abortion [153, 161, 170]. Psilocin is associated with breakdown of the BBB. A 33-year-old patient developed left leg weakness and visual field defects 2 weeks after magic mushroom consumption which was attributed to multifocal cerebral demyelination within the corpus callosum and both optic nerves [171].

The first effects of intoxication with *A. muscaria* and *A. pantherina* are muscarinic: nausea, vomiting, diarrhea, vasodilation, sweating, and salivation [84, 172, 173]. Thirty minutes after ingestion, anticholinergic signs and

symptoms arise, including mydriasis, xerostomia, hyperthermia, a slight blood pressure increase, drowsiness, memory loss, dizziness, photophobia, euphoria, motor hyperactivity, hallucinations, and delirium [84, 172–174]. These tend to intensify over 2–3 h. Somnolence followed by deep sleep and skeletal muscle atony and hyporeflexia follows, a state which can resemble a stroke [84]. A study of human volunteers found that hallucinations, muscle twitching, delirium, and sleep occurred after pure ibotenic acid and muscimol administration [175]. Signs of poisoning decrease after about 8 h [84, 172, 173, 175, 176].

Muscle twitching, spasms, cramps, abdominal pain, and seizures can result from intoxication with fly agaric, especially in children [123, 175, 177]. Animal studies show that ibotenic acid administration systemically or locally can induce seizures [178, 179]. The LD₅₀ of muscimol in rats is 4.5 mg/kg after intravenous administration and 45 mg/kg after oral administration. For mice, the LD₅₀ is 2.5 mg/kg intraperitoneally, 3.8 mg/kg subcutaneously, and 5.62 mg/kg intravenously [180, 181]. The oral LD₅₀ in rabbits is 10 mg/kg. For ibotenic acid, the LD₅₀ in rats is 128 mg/kg orally and 42 mg/kg intravenously and for mice 38 mg/kg orally and 15 mg/kg intravenously [180]. Cortical injections of ibotenic acid are used to model Alzheimer's disease in rats given its cytotoxicity [182].

Bufotenine

As stated previously, because of its poor penetration of the blood–brain barrier, bufotenine (5-hydroxydimethyltryptamine), found in many toad and plant species, is not believed to be psychoactive if ingested. One species of toad, the Sonoran Desert (also known as Colorado River) toad (see Fig. 2) *Bufo alvarius*, is unique within its genus, however, in possessing the enzyme *O*-methyltransferase, which converts bufotenine to the potent hallucinogen 5-methoxydimethyltryptamine [183]. A 5-year-old boy was reported to have developed profuse salivation and status epilepticus within 15 min of licking a toad identified positively as *B. alvarius*

Fig. 2 The Colorado River Toad (*Bufo Alvarius*) (Source U.S. National Park Service)

[96]. He survived but remained symptomatic for 1 week. It has been shown that inhalation of the vaporized venom results in an intense but short-lived “trip” after 15 s, marked by auditory and visual hallucinations [183]. This mode of intake apparently denatures the venom's more toxic fractions, avoiding serious toxicity. Toad venoms contain many toxic substances in addition to indolealkylamines (bufotenines), including biogenic amines (epinephrine, norepinephrine), cardioactive steroids similar to digitalis (bufotalins or bufogenins), and conjugates of bufogenins (bufotoxins) [184].

Dimethyltryptamine

The prevalence, user characteristics, and abuse potential of dimethyltryptamine were recently reviewed [65]. Intramuscular administration of DMT produces visual hallucinations and illusions, distortions of spatial perception and body image, thought disturbance and euphoria [185], visual and auditory hallucinations, and bodily dissociation [186]. DMT is known to produce sympathomimetic effects including tachycardia, hypertension, and mydriasis [185–187].

Symptoms of DMT intoxication include cognitive changes described as “deep introspection” [188]. DMT can be snorted, ingested, or smoked, but the latter is the most commonly utilized, likely owing to improved clinical effect. DMT was

found in one study to have a shorter duration of effect compared to LSD, ketamine, and magic mushrooms (23.8 ± 33.9 min) and was judged by users to have the strongest effect and deemed as pleasurable as LSD, more pleasurable than ketamine or magic mushrooms, with the fewest negative effects attributed to its being smoked.

Ayahuasca Brew

Oral intake of ayahuasca brew, a botanical hallucinogenic preparation, is associated with nausea and vomiting [65]. Ayahuasca has been associated with severe intoxication, though some reports lack sufficient supporting forensic/toxicological information. Available case experience suggests patients with cardiac or liver disease are especially susceptible to toxicity and that co-ingestion of other serotonergic agents also poses an additional risk [189].

5-Methoxy-*N,N*-Dimethyltryptamine

5-MeO-DMT is a potent, fast-acting hallucinogen of short duration. It can be used by inhalation and injection, sublingually, intranasally, or orally [69]. 5-Methoxy-*N,N*-dimethyltryptamine has high affinity for the 5-HT_{1A} receptor, 4–10 times more potent than DMT [190, 191]. It causes visual and auditory changes, distorting perception of time 3–4 min after it is inhaled, effects which peak after 35–40 min and last 60–70 min [192]. Because of the first-pass effect, oral administration produces no effect. Oral coadministration with harmaline is about one-third as potent as administration via the intranasal or sublingual routes. Animal models of 5-MeO-DMT toxicity document symptoms including ataxia, mydriasis, head nodding, tremor, convulsions, and shivering [193, 194]. Bufotenine has 5–10 times greater affinity for 5-HT_{2A} receptors than 5-MeO-DMT but poor penetration of the blood–brain barrier. Its administration intravenously, intranasally, or sublingually results in psychoactive effects [71, 195, 196].

Ibogaine

Among the natural IAA hallucinogens, ibogaine has proven to be particularly toxic. Overdose of ibogaine resulted in altered mental status, sinus bradycardia, QTc prolongation, brief self-limited episodes of polymorphic tachycardia initially associated with tonic–clonic seizures deteriorating into torsades de pointes, and cardiac arrest. The patient responded initially to defibrillation, but torsades recurred despite intravenous magnesium, atropine, epinephrine, and isoprenaline. The patient was defibrillated several more times and intubated, and first transcutaneous then transvenous pacing shortened his QTc and prevented return of dysrhythmia [197]. It is believed that ibogaine causes QT interval prolongation by blocking human ether a-go-go-related potassium channels during their activation during cardiac repolarization. When studied in mammalian kidney tsA-201 cells, the mechanism appeared to result from preferential binding of ibogaine to the open and inactivated state of the cytosolic side of the channel resulting in a shift of steady-state activation and inactivation to more negative membrane potentials [198]. Though the proximate cause was not determined for this case, ibogaine when used as an alternative medicine in alcohol detoxification with documented serum level elevation was associated with sudden death in a patient who on autopsy was found to have hepatic cirrhosis and heavy fatty infiltration [199].

The clinical presentation of patients intoxicated with other indolealkylamine hallucinogens is similar to the presentations described earlier for LSD and psilocybin. One exception, though, is ibotenic acid which can cause convulsions and hyperexcitability similar to its endogenous analogue glutamate [58]. The main long-term risk of abuse of hallucinogens is impairment of mental functioning and psychosis [200]. A subset of users can have persistent symptoms long after stopping drug use [201]. Users have called this persistent drug trips or “flashbacks,” labeled in the American Psychiatric Association’s Diagnostic and Statistical manual V (DSM-V) as “Hallucinogen Persisting Perception Disorder” (HPPD) (APA DSM-V, 2013, ICD-10-CM F16.983). Reported

symptoms are generally visual, but auditory symptoms can occur. The diagnosis is difficult given the existence of other conditions which alter perception and no specific diagnostic test to identify HPPD [202].

Diagnosis

The differential diagnosis of severe poisoning with the indolealkylamines includes intoxication with the phenylalkylamine (e.g., amphetamine derivatives) or cycloarylhexyl (e.g., phencyclidine) hallucinogens, which present in a similar manner, with the exception that small fixed pupils and nystagmus can be prominent distinguishing features of phencyclidine (and congener) intoxication. Other toxicologic causes in the differential diagnosis include anticholinergic poisoning (e.g., jimsonweed, scopolamine), sympathomimetic poisoning (e.g., cocaine), the serotonin syndrome, malignant hyperthermia, and neuroleptic malignant syndrome. Possible nontoxicologic causes with similar signs and symptoms include psychosis, central nervous system infections, withdrawal syndromes, and delirium from metabolic causes.

The diagnosis of indolealkylamine poisoning depends first on the acquisition of a thorough history if available. Smoking or licking of toad venom, use of blotter “acid,” or ingestion of “psychedelic mushrooms” suggests the diagnosis. Adult patients with uncomplicated hallucinogenic experiences usually do not present to health-care facilities. Adults who do present to health-care facilities usually have presentations similar to those described in the prior section. Hallucinations, fixed and dilated pupils, muscle rigidity, and hyperthermia in the absence of other explanations should raise a high index of suspicion for this type of intoxication. Given the possibility of co-ingestion of an MAO-A inhibitor in those using IAAs recreationally, the possibility of serotonin syndrome should be considered especially in patients with severe manifestations such as delirium, neuromuscular rigidity, and/or hyperthermia (see ► Chap. 24, “Serotonin Syndrome”). Evaluation of a patient with hallucinations should include an electrocardiogram with measurement

of the QT interval given the possibility of its prolongation and resulting life-threatening arrhythmias in the context of ibogaine intoxication.

Standard drug-of-abuse screening tests do not detect these agents. LSD and its major metabolite, 2-oxy-LSD, remain in the urine for 12 h and can be detected by specific directed radioimmunoassay [145]. LSD degrades on exposure to light, so specimens should be wrapped in opaque paper or aluminum foil and frozen. Identification of hallucinogenic mushrooms requires a proper specimen and the services of an experienced mycologist. Exposure to a toad in the area of the Sonoran Desert should raise suspicion of toad toxicity. The toad should be identified if available. Liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) has been used to sensitively and reliably quantitate blood 5-MeO-DMT and bufotenine levels [68]. Effective liquid chromatography–mass spectrometry methods to detect psilocybin and psilocin have been developed, but are not routinely available in a clinically meaningful time period [58]. Thin-layer chromatography can be used for qualitative identification of ibotenic acid. High-performance liquid chromatography (HPLC) (reversed phase) can be used to quantitate ibotenic acid or muscimol [203–205].

Treatment

Treatment of intoxication by indole hallucinogens does not routinely require gastrointestinal decontamination with activated charcoal but may include it if the patient presents soon after oral ingestion, particularly if there is concern for co-ingestants. However, there are no data indicating that it alters the clinical outcome in these patients. Activated charcoal should be given cautiously, if at all, to patients who may develop seizures or altered mental status for to avoid aspiration. Gastric lavage, considered to be of very limited utility, if any, in the management of poisoned patients in general, should be avoided in patients intoxicated by indole hallucinogens. These procedures are unlikely to be beneficial and could

worsen the agitation of the patient as well as increase the possibility of serious adverse events such as aspiration. Extracorporeal removal techniques play no role in the treatment of poisoning with the indolealkylamines.

Specific treatments have been reported to be helpful for various complications of indolealkylamine intoxication. Hyperanxiety states and panic attacks are helped by treatment with someone at bedside in a quiet room with a soothing, reassuring, nonjudgmental approach (Level III recommendation). Patients are “talked down” by repeated orientation to person and place, explaining that symptoms are drug related and the patient is not losing their sanity [146] (Level III recommendation). Given the serotonin receptor agonism of indoles, serotonin reuptake inhibitors logically should be avoided. Benzodiazepines are likely to be beneficial if sedation is required [145] or if treatment is needed for sympathetic excess (Level II-III recommendation).

Among the most dangerous complications of IAA intoxication is serotonin syndrome (see ► Chap. 24, “Serotonin Syndrome”), made more likely when co-ingestion with an MAO-I occurs, and especially life-threatening when accompanied by the severe hyperthermia which can result. It is recommended that patients with serotonin syndrome and severe hyperthermia (temperature is more than 41.1 °C) be treated with sedation, neuromuscular paralysis, and orotracheal intubation [206] (Level III recommendation). There is no role for antipyretics since temperature elevation in this context results from muscular hyperactivity rather than a derangement of the hypothalamic set point.

There is evidence to suggest that the rate of cooling in hyperthermia is an important determinant of mortality. A retrospective study of non-exertional heatstroke found a statistically nonsignificant trend toward increased mortality for patients whose cooling to a temperature of less than 38.9 °C (102 °F) was delayed more than an hour compared to patients cooled to that temperature within an hour of presentation [207]. No controlled clinical trials exist to guide selection of method or endpoint for temperature reduction in drug-induced hyperthermia. However,

guidelines recommended for heat stroke include lowering the core temperature to <39.4 °C by promoting heat loss by conduction and evaporation, maintaining a skin temperature of 30–33 °C to avoid vasoconstriction, control of any seizures, airway protection and maintenance of oxygenation (saturation > 90%), intravenous fluids and pressors as appropriate to maintain vital organ perfusion (MAP > 60 mmHg), volume expansion +/- furosemide, mannitol or bicarbonate to prevent myoglobin-induced renal injury, and monitoring and maintenance of electrolyte (K^+ , Ca^{++}) balance to prevent life-threatening arrhythmias [208]. Two cases of severe drug-induced hyperthermia, one from an amphetamine derivative and another from cocaine, were cooled using ice-water submersion. The observed cooling rates were faster than those previously reported for the mist and fan technique [209].

Because it has been suggested that hallucinogens are psychoactive because of their affinity for 5-HT₂ receptors, treatment of toxicity from these agents may benefit from the use of 5-HT₂ receptor antagonists [210]. Cyproheptadine is given for serotonin syndrome orally or crushed via nasogastric tube in a dose of 12 mg, followed by 2 mg every 2 h until clinical response is seen [206]. Its administration is associated with sedation and transient hypotension responsive to intravenous fluids. Although there are reported human cases of benefit from cyproheptadine in serotonin syndrome [210–215], animal data suggest that a pure 5-HT₂ antagonist might be more effective. In a fatal rat model of serotonin syndrome, treatment with chlorpromazine and cyproheptadine prevented lethality only at high doses [216]. However, the potent 5-HT_{2A} receptor antagonists ritanserin and pipamperone prevented lethality and increase in temperature while muting the associated rise of hypothalamic norepinephrine better than the other treatments. Both are available for oral use, though their therapeutic use in humans for serotonin syndrome is undocumented. In another study using a lethal rat model of serotonin syndrome, the potent 5-HT_{2A} antagonist, risperidone,

prevented serotonin syndrome and mortality as did ketanserin, a selective 5-HT_{2A} antagonist [94]. Of interest, in the same study, animals given the D₂ antagonist, haloperidol, died sooner than saline control animals.

Care should be taken in treating tachycardia and hypotension in the context of serotonergic excess and even more so if co-ingestion of an MAOI is suspected. Hypertension and tachycardia can be transient and fluctuating in this context, so short-acting intravenous agents such as nitroprusside and esmolol are preferred. If pressors are used to treat hypotension in the context of co-ingestion with an MAOI, indirect agents such as dopamine should be avoided given the exaggerated catecholaminergic response which can result [206]. Direct agonists such as phenylephrine, epinephrine, or norepinephrine are preferred (Level III recommendation).

Indications for ICU Admission in Indole

Hallucinogen Poisoning

Respiratory depression requiring mechanical ventilation
Hyperthermia requiring external cooling
Muscle rigidity/hyperthermia requiring neuromuscular blockade
Myoglobinuric renal failure
Hypertensive crisis
Malignant arrhythmia
Seizures/status epilepticus

Criteria for ICU Discharge in Indole

Hallucinogen Poisoning

Adequate oxygenation and ventilation without ventilator support
Normalization of vital signs (tachycardia, hypertension) without pressor or inotropic support
Core temperature <39 °C with no evidence of life-threatening end-organ damage*:
No evidence of cerebral edema, hemorrhage or infarction, and seizures
No evidence of pulmonary aspiration or edema
No evidence of cardiac failure or infarction

No evidence of hepatic or renal injury
No evidence of rhabdomyolysis
No evidence of disseminated intravascular coagulation

*Should end-organ damage occur, timing of intensive care unit discharge is situation dependent.

Special Populations

Pediatric Patients

Given the reemergence of hallucinogen use among teenagers and the availability of unsupervised access to information regarding synthesis and administration of these agents on the Internet [217], heightened awareness of the presentation and knowledge of treatment of toxicity from these agents are needed. There is no evidence basis for a different approach in the pediatric population to indolealkylamine poisoning. Per the 2014 NPDS report, there was no pediatric mortality from hallucinogens until adolescence when there were deaths from hallucinogen amphetamines [41].

Pregnant Patients

Available data concerning use of these agents in pregnancy are inconclusive. A review of the genetic toxicity of LSD found the available information on teratogenicity to be contradictory and inconclusive [218].

Common Errors in Indole Hallucinogen Poisoning

Exacerbating agitation in hallucinogen intoxication from overaggressive gastrointestinal decontamination
Failure to recognize and treat hyperthermia aggressively

(continued)

Overlooking therapy to limit renal effects of myoglobin in treating hyperthermia
 Treatment-induced hypertension from use of β -blockers for psychostimulant-induced hypertensive crisis
 Mistaken use of serotonin reuptake inhibitors or phenothiazines in indolealkylamine-induced hyperthermia

Key Points in Indole Hallucinogen Poisoning

1. Intoxication with indolealkylamines in most instances responds to reassurance and good supportive care
2. Serotonergic excess from these drugs requires aggressive treatment: hyperthermia necessitates active external cooling, benzodiazepines, neuromuscular blockade, and possibly serotonin (5-HT₂) receptor antagonists
3. Consultation with an experienced mycologist may be necessary to confirm *Psilocybe* mushroom poisoning (and rule out hepatotoxic mushroom ingestion) if there is any concern for the latter

Cannabinoids are a diverse group of synthetic and naturally occurring molecules that interact with endogenous human cannabinoid receptors. The clinical effects of cannabinoids are varied and depend upon the individual cannabinoid molecule, the specific cannabinoid receptor (CR) that is agonized, and the route of cannabinoid exposure.

There are many cannabinoids that cause clinical effects. Plant-derived cannabinoids (phytocannabinoids) are most commonly found in *Cannabis* spp. plants, commonly known as marijuana. Cannabis is produced in virtually every country and is the most commonly abused illicit drug worldwide. Approximately 25% of worldwide production occurs in Africa closely followed by North and South America which produces approximately 23% of the world's cannabis [1]. Cannabis products are increasingly available throughout the USA as some states have legalized the use of medical and/or recreational marijuana products. This increased availability has led to increased rates of hospitalization associated with cannabinoid ingestion [3].

Synthetic cannabinoids (SC) are a heterogeneous group of molecules that are agonists at CRs. They were first developed as research tools to study the endocannabinoid system and subsequently for therapeutic purposes [8]. However, the emergence of significant adverse effects, especially neuropsychiatric effects, caused most to be quickly abandoned as therapeutic agents. They are increasingly produced in clandestine

laboratories and abused worldwide [9]. Because the production is illicit, locations of manufacture are difficult to ascertain though a significant proportion of SCs are believed to originate from Chinese laboratories [10]. SC use results in higher rates of medical morbidity than marijuana products; new chemical variants have resulted in numerous public health outbreaks characterized by renal injury/failure, seizures, and occasionally, death [5, 6, 11–13].

There are dozens of SCs with additional novel SC molecules identified every few months [9, 10, 13]. The predominant demographic characteristics of users are males between 20 and 30 years of age [9, 14]. SCs are the second most abused illicit drug after marijuana in adolescents [15] and are commonly abused by active military service members [16, 17]. Reports of abuse to international poison centers have increased every year since 2008 [5, 14, 18]. Thus, SCs are the most commonly abused synthetic designer drug and fastest growing drug of abuse [19].

Biochemistry and Clinical Pharmacology (Includes Pharmacokinetics)

Endogenous Cannabinoid Receptors and Agonists

The endocannabinoid system consists of cannabinoid receptors and cannabinoid agonists.

Endogenous cannabinoid receptors are found throughout the human body including the brain, solid organs, connective tissue, and immune system including the thymus, tonsils, B lymphocytes, T lymphocytes, macrophages, monocytes, natural killer (NK) cells, and polymorphonuclear cells [20–22]. The best characterized receptors are the cannabinoid receptor 1 (CB1) and the cannabinoid receptor 2 (CB2) though the transient receptor potential cation channel subfamily V member 1 (TrpV1, capsaicin receptor) and the G-protein-coupled receptor 55 (GPR55) have been demonstrated to play a role in endocannabinoid signaling

[23, 24]. CB1 is a G-coupled protein that is expressed in the nervous system and the periphery. Activation of the receptor triggers a variety of downstream processes mediated through inhibition of adenylate cyclase and subsequent decrease in intracellular cAMP [25]. Clinical intoxication by cannabinoids is mediated through this pathway [26–28]. Additional cannabinoid receptors, such as CB-2, TrpV1, and GPR55, are found throughout the body and likely contribute to organ-specific toxicity.

Toxicity from inhalation cannabis is dose dependent, peaks around 30 min, and resolves over 2–6 h. Edible cannabis products have significantly delayed kinetic parameters, onset occurs at approximately 30 min, serum peak occurs between 2 and 3 h, and clearance occurs in 8–12 h [29]. See Box [Pharmacokinetics](#) for kinetic parameters associated with cannabinoids products.

Endocannabinoid agonists are derived from integral components of cell membranes; they act as hydrophobic lipid messengers. These molecules activate CBs locally or on nearby cells. These messengers are made on demand and act as retrograde messengers and synaptic modulators [22]. The major endogenous cannabinoid neurotransmitters are anandamide and 2-arachidonoylglycerol. Abused SCs uniformly have a higher affinity [30–32] and higher potency [5, 6, 33] at the CB1 than delta-9-tetrahydrocannabinol (THC) and the endogenous cannabinoid neurotransmitters. In addition, some SCs, such as WIN55,212-2, inhibit serotonin and dopamine uptake leading to higher levels of these neurotransmitters within the synapses and at the neuromuscular junction [34, 35]. Subsequently, the clinical effects elicited by SCs are less predictable than the phytocannabinoids, potentially leading to more toxicity. Depending upon the SC molecule, potency at the CB1 receptor ranges from full agonism to antagonism [36].

The prototypical SC was WIN55,21-2, an aminoalkylindole cannabinoid that inspired the production of indole cannabinoids [37]. This compound binds CB2 with more affinity than CB1. Naturally, alternative indole molecules with greater CB1 affinity were soon developed

[38]. Pyrrole derivatives of the molecule resulted in variable affinities for the CB1 receptor depending upon the length of the R1 side chain; longer side chains lead to greater CB1 affinity [39]. Addition of a phenyl group to the pyrrole molecules led to variably increased CB1 binding affinity, depending upon the substitution location [38]. Potency is further increased via cyclic stacking of the naphthoyl indole molecules at the CB1 receptor [40]. The newest and most SCs to date are the indazoles, such as AB-FUBINACA and ADB-PINACA, which uniformly have higher CB1 and CB2 binding affinity [41]. Toxicity has increased as the CB1 affinity and the potency of these molecules have increased [13, 41, 42].

Pathophysiology of Toxic Effects

Excessive activation of central and peripheral cannabinoid receptors results in toxicity. Activation by endocannabinoids, THC, and SCS inhibits adenylate cyclase which subsequently decreases intracellular cAMP. This, in turn, increases conductance through calcium-dependent potassium channels [43–45]. This leads to the release of acetylcholine, L-glutamate, gamma-aminobutyric acid, norepinephrine, dopamine, and 5-hydroxytryptamine. The increased release of these neurotransmitters results in central nervous system (CNS) toxicity and may contribute to organ-specific toxicity.

Clinical Presentation and Life-Threatening Complications

Clinical presentation from cannabinoid agonists consists primarily of neurotoxicity. However, additional organ toxicity occurs as a result of local agonism of CBs and as a manifestation of neurotoxicity, for example, progressive acidemia due to seizures has led to renal tubular acidosis [46]. See Table 1 for clinical features resulting from acute cannabinoid agonist toxicity.

Clinical Toxicity from Phytocannabinoids

The majority of patients presenting with evidence of toxicity from naturally occurring cannabinoid products demonstrate central nervous system (CNS) toxicity in the form of agitation followed by CNS depression and neuropsychiatric features [7]. THC causes psychosis, even those without underlying psychiatric disease, and the symptoms increase with increased dose [47–49]. CNS depression seems to predominate in children [50]. While adult patients very rarely require critical care for ingestion of *Cannabis* spp. products, young children may require monitoring in an intensive care setting, and occasionally endotracheal intubation, for airway protection [50, 51]. Edible THC products disproportionately result in more medical presentations for toxicity. This is likely due to the unpredictable dosing and the delayed clinical effects resulting in “dose stacking” by users [3].

Synthetic Cannabinoids

While naturally occurring cannabinoids rarely lead to severe clinical illness, synthetic cannabinoid products may result in organ failure and have resulted in intensive care unit admission in approximately 15% of cases during several outbreaks [6, 13, 52]. While the clinical features and organ toxicity are diverse dependent upon the specific SC(s) involved, neurotoxicity generally predominates. This is characterized by delirium and seizures in the acute phase. Patients typically demonstrate a hyperadrenergic state characterized by tachycardia, hypertension, and occasionally hyperthermia during this phase. After 3–6 h, CNS depression predominates. Patients may develop bradycardia during this phase, similar to cocaine washout syndrome. The vast majority of severely poisoned patients recover completely over 12–24 h, with good supportive care.

Table 1 Life-threatening clinical symptoms and management^a

System	Clinical effects	Management
Central nervous system	Excitotoxicity characterized by agitation, hallucinations, and seizures [6, 13, 53]. There have been cases of acute ischemic cerebral vascular accidents [12]	Benzodiazepines, antipsychotics, and GABA agonists
Pulmonary	Aspiration risk in children and severely poisoned adults [3, 50]. Nonspecific organizing pneumonia with a tree-in-bud pattern may occur with SC inhalation [54]	Airway management to prevent aspiration. Cessation of use of these agents
Cardiac	Bradycardia has been demonstrated with several SCs [6, 11]	Bradycardia can be treated with electrolyte repletion and observation. While unlikely, bradycardia leading to impaired organ perfusion can be treated with atropine 0.5 mg IV
Gastrointestinal	Nausea and vomiting are common presenting complaints for both marijuana and SCs [5, 55]	Antiemetics and antipsychotics can be used to control nausea and vomiting. Ondansetron 4–8 mg IV bolus, metoclopramide 5–20 mg IV bolus, and haloperidol 2.5–10 mg IV bolus. These agents may be given as often as needed until symptoms are controlled or until limited by toxicity of the treatment
		Heavy users that develop cannabinoid hyperemesis syndrome report acute improvement of nausea with hot showers though the only proven cure is cessation of marijuana use [56]
Hepatic	There are no definitive reports of cannabinoid-induced hepatotoxicity	NA
Renal	Acute tubular necrosis and interstitial inflammation have been seen with SC abuse [46, 57]	Hemodialysis should be employed for severe metabolic acidosis, severe electrolyte abnormalities, or oligo/anuria. Fluid resuscitation with isotonic fluids should be employed aggressively for oliguria
Musculoskeletal	Rhabdomyolysis [58, 59]	Fluid resuscitation
Dermal	Marijuana may lead to hypersensitivity dermal reactions, particularly in workers [60]. There are no reports of progression to Stevens-Johnson syndrome or toxic epidermal necrolysis	Removal of the allergen. Topical steroids such as fluocinonide topical 0.1% daily

^aAll medical management recommendations should be considered Level 3 evidence and are based upon case series, case reports, and clinical experience of the author

Diagnosis

The diagnosis of cannabinoid intoxication is based upon clinical history. Marijuana can be detected by the majority of clinically available qualitative urine immunoassays. These immunoassays typically detect 11-nor-THC-9-carboxylic acid (THC-COOH), a pharmacologically inactive metabolite of parent THC. Chronic users may have THC-COOH detected in the urine for

greater than a month [61–63]. False positives for THC due to nonsteroidal anti-inflammatories, antiemetics, proton pump inhibitors, and other agents have been reported (see “Drugs Known to Cause False Positives on THC Immunoassays”) [64, 65]. Confirmation of the qualitative immunoassay can be performed with liquid or gas chromatography and mass spectrometry (LC or GC-MS). A clinician may infer the timing of ingestion based upon the parent compound/metabolite ratio detected with liquid

chromatography tandem mass spectrometry (LC-MS/MS) methodologies though this inference is prone to individual variability and is not recommended in routine clinical practice. This is not clinically useful since patients recover rapidly though the LC-MS/MS testing may be useful in legal settings. Further, most clinical laboratories do not conduct LC-MS/MS testing in-house, making the results unavailable in a clinically useful timeframe.

In contrast, clinical immunoassays almost uniformly do not detect synthetic cannabinoid receptor agonists [66]. Several reference laboratories now offer blood, urine, and saliva LC-MS/MS assays for a variable panel of synthetic cannabinoid receptor agonists. However, these panels are not comprehensive; additionally, minor alterations in the chemical structure can yield false negatives on these assays because these new SCs do not have verified standards for the LC-MS/MS method leading to delay molecular identification. The rapid evolution of new SCs, and the resulting lack of reliable analytical standards, hampers the laboratory detection and identification of these agents.

Drugs Known to Cause False Positives on THC Immunoassays

Ibuprofen
Naproxen
Ketoprofen
Niflumic acid
Promethazine
Riboflavin
Dronabinol
Pantoprazole
Omeprazole
Esomeprazole
Efavirenz
Baby soaps

Treatment

Supportive care is the mainstay of treatment for cannabinoid toxicity. Most patients with CNS depression alone can be observed without

intervention. Agitated patients may require benzodiazepines and/or antipsychotic medication to prevent harm to themselves or others. IV boluses of benzodiazepines such as lorazepam (0.05–0.1 mg/kg), midazolam (0.05–0.1 mg/kg), or diazepam (0.1–0.5 mg/kg) may be used in conjunction with antipsychotics. Appropriate antipsychotic medications for cannabinoid toxicity may include haloperidol 5–10 mg, droperidol 2.5–5 mg, or olanzapine 5–10 mg IV boluses. Benzodiazepines are favored in patients also manifesting seizure activity. These doses may be repeated every 5–15 min, as needed to halt seizures and provide adequate sedation.

Patients with recurrent seizures or status epilepticus should be intubated and sedated with a GABA agonist such as propofol (Grade I recommendation).

Special Populations

Young children with CNS depression may be at risk for airway obstruction and aspiration [50]. In addition, children more commonly ingest the product, often a large dose, leading to prolonged toxicity. Monitoring in an intensive care setting is warranted for many symptomatic toddlers following exposure. Asymptomatic children may be medically cleared after 6 h of observation.

Indications for ICU Admission

- Toddlers with CNS depression requiring airway monitoring
- Recurrent seizures
- Hemorrhagic or ischemic cerebrovascular accidents

Criteria for ICU Discharge

- Lack of seizure activity for 6+ hours
- Adequate protection of airway manifested as easy arousal with appropriate verbal communication

Key Points

- Synthetic cannabinoids are more potent and lead to more severe acute toxicity than phytocannabinoids.
- Ingestion of marijuana edibles results in presentation for toxicity more often than inhalation.
- Children are at risk of airway compromise due to cannabinoid ingestion.

Pharmacokinetics

- Inhalation of marijuana [2]
 - Onset: <10 min
 - Peak: 30–90 min
 - Elimination: 4 h
- Ingestion of marijuana edibles [2]
 - Onset: 30 min
 - Peak: 3 h
 - Elimination: 12 h
- Inhalation of synthetic cannabinoids [4–7]
 - Onset: <10 min
 - Peak: 30–90 min
 - Elimination: 4–12 h (active metabolites)

Antimony

Antimony (stibium [Sb]) is a brittle, crystalline, silver-white metalloid naturally present in the Earth’s crust and found at low levels throughout the environment. At least 114 different ores have been identified [1]. Stibnite (SbS_3) is the predominant ore; the others are mostly oxides.

Antimony has been used by human civilization for millennia. Al-kohl, antimony powder used as a cosmetic, is the etymological origin of the word alcohol [1]. The ancient Romans used antimony compounds as emetic drugs (*calices vomitorum*) and expectorants [2]. In the fourteenth century, John of Rupescissa used it as an alternative to bleeding to remove toxins from the body, a use subsequently promoted by Paracelsus. The Danish physician Severin described the effects of ingested antimony as “vomare, cacare, sudare,” reflecting its ability to cause vomiting, diarrhea, and sweating. In the nineteenth century, antimony potassium tartrate (“tartar emetic”) was used in the treatment of schistosomiasis [3].

Two pentavalent antimony-containing drugs, sodium stibogluconate (US trade name Pentostam[®]) (US trade names are given herein as examples; they may be the same, or different, in other countries) and meglumine antimoniate (US trade name Glucantime[®]), have until recently been the mainstays for treatment of visceral, mucosal, and cutaneous leishmaniasis (kala-azar) [4, 5]. Sodium stibogluconate is largely used in English-speaking countries, while meglumine

antimoniate is used in French- and Spanish-speaking countries [6].

Elemental antimony is used in the production of semiconductors, infrared detectors, and diodes [7]. Antimony commonly is alloyed with other metals, such as lead, copper, and silver, to increase their hardness, mechanical strength, and corrosion resistance and to decrease their coefficient of friction. The common forms of antimony found in industry are antimony trioxide, pentoxide, trisulfide, oxysulfide, pentasulfide, and trichloride. Antimony trioxide is used as a fire retardant for plastics, textiles, rubber, building materials, adhesives, pigments, and papers, while antimony trisulfide is used in the manufacture of lead batteries, type metal, paints, ceramics, and glass [8, 9].

Biochemistry and Clinical Pharmacology

Antimony (atomic number 51, atomic weight 121.76) is found in group VA (formerly group 15) of the periodic table of elements, directly below arsenic and above bismuth. Antimony has been described as less toxic than arsenic but more toxic than bismuth [10]. It has four oxidation states: 0, +3, +5, and -3 ; the +3 state is the most common [11]. Pentavalent antimony is more commonly found in aerobic conditions, while trivalent antimony is more commonly found under anaerobic conditions and as a consequence of human activities [7]. The important toxicologic properties of antimony and common antimony-containing compounds are presented in Table 1.

In contrast to the closely related element arsenic, available human data regarding the toxicology of antimony compounds are sparse and are derived mainly from animal studies, occupational exposures, and patients treated with antimony potassium tartrate (Sb(III)), sodium stibogluconate (SB(V)), and meglumine antimoniate (SB(V)). Evaluation of toxicity is further complicated by the fact that antimony is frequently found in association with other potentially toxic materials, including lead and arsenic. The word antimony is derived from the Greek “anti” and “monos,” meaning “not alone.”

Soil antimony concentrations are typically less than 1 ppm, although soil near antimony processing sites or hazardous waste sites on the US Environmental Protection Agency’s National Priorities List may have concentrations as high as 2550 ppm [12]. Airborne concentrations range from 1 to 170 ng/m³ [7]. Antimony can be found dissolved in water at concentrations less than five parts per billion (ppb), typically attached to particles of dirt. The average human daily intake is 5 mcg, reflecting levels of 0.2–1.1 ppb in food sources [13].

Antimony compounds are poorly absorbed (15%) and readily excreted [10]. The absorption of antimony from the respiratory tract depends on particle size and water solubility, with aerosols containing small particles of low water-solubility compounds (e.g., antimony oxides) retained in the lungs for longer periods than larger particles with higher water solubility (e.g., antimony tartrate) [14–16]. After oral ingestion, less than 10% of antimony tartrate and 1% of all other forms of antimony are absorbed [17]. Valence states determine the distribution of antimony in blood and tissues [15, 18]. After inhalation, the trivalent and pentavalent forms concentrate in the erythrocytes and plasma. Antimony has been reported to accumulate in the liver when absorbed in the trivalent form and in the skeleton when given in the pentavalent form, although different distribution patterns were noted by other authors [14–16]. Similar to the distribution pattern after inhalation, the distribution of antimony after gastrointestinal absorption also seems to depend on valence state [19]. Parenterally administered antimonial drugs demonstrate poor skin bioaccumulation, resulting in the need for different treatment regimens for cutaneous leishmaniasis as compared with visceral leishmaniasis [6]. The volume of distribution is greater in trivalent than pentavalent compounds. Studies on patients receiving antimonial therapy for leishmaniasis revealed a volume of distribution of 0.22 ± 0.05 L/kg [20]. Pentavalent antimony is excreted preferentially in urine; the trivalent forms are excreted in the feces [21, 22].

Pentavalent compounds are considered less toxic than trivalent compounds, acting as prodrugs

Table 1 Properties of antimony and common antimony compounds^a

Property	Antimony	Antimony pentasulfide	Antimony pentoxide	Antimony potassium tartrate

^gBecause these substances exist in the atmosphere in the particulate state, the concentration is expressed as mg/m³

that require biological reduction to the active trivalent form [23]. The site and mechanism of reduction of Sb(V) within the amastigote remain controversial [23]. Particularly, in acidic environments, both glutathione and trypanothione can reduce Sb(V) to Sb

(III) nonenzymatically [24, 25]. The presence of an intracellular antimony reductase has also been proposed [26]. In humans, the reduction of antimony appears to occur at low levels, with only 5–10% Sb (V) converted to Sb(III) [27].

A two-compartment pharmacokinetic model has been proposed to describe the fate of antimony after being administered intramuscularly in the pentavalent form, consisting of a fast phase and a slow phase with elimination half-lives of 2.02 ± 0.25 h and 76 ± 28 h, respectively [20]. The slow terminal elimination phase was hypothesized to be due to conversion of Sb(V) to Sb(III). In rhesus monkeys, the terminal elimination phase half-life during a 21-day course of meglumine antimoniate therapy was found to be 35.8 days [28]. Posttreatment, antimony is localized within the liver, thyroid, and nails. In contrast to arsenic, methylation of antimony is limited, suggesting that Sb(III) is less effectively detoxified than As(III) [27]. Within the rat, Sb(III) is conjugated with glutathione and excreted in the bile [29]. The antimony-glutathione bond was noted to be unstable, with potential for enterohepatic reabsorption of Sb(III). More than 80% of intravenously administered stibogluconate was excreted in the urine within 6–8 h [30]. The half-life of antimony in urine is approximately 95 h [31].

Pathophysiology of Toxic Effects

Being chemically, physically, and physiologically similar to arsenic, antimony toxicity is similar to arsenic toxicity [32]. As with other metals, antimony interacts with sulfhydryl groups of enzymes and other proteins. In vitro, antimony inhibits succinic oxidase, pyruvate oxidase, and phosphofructokinase, suggesting interference with cellular respiration [2, 33]. In guinea pigs, trivalent antimony is able to prolong the action potential of ventricular myocytes by increasing calcium currents, possibly through interactions with calcium channel cysteine residues in a mechanism analogous to arsenic trioxide [34, 35]. Anti-leishmanial effects are attributed to depletion of intracellular ATP due to interference with glycolysis and beta-oxidation of fatty acids in amastigotes [36]. The generation of reactive oxygen species has also been postulated to play a role in antimony toxicity [37]. Antimony-associated apoptosis is attributed to depletion of glutathione capacity and subsequent enhancement of reactive oxygen species formation [38, 39].

Clinical Presentation and Life-Threatening Complications

Antimony poisoning may occur in the industrial and occupational setting, primarily with exposures to trivalent forms (antimony trioxide, trisulfide, and trichloride) and in patients treated with pentavalent antimony compounds for leishmaniasis. Numerous organ systems are involved in antimony toxicity and may vary with the route of exposure (inhalation vs. ingestion vs. parenteral administration).

Antimony is historically known for its emetic properties after oral ingestion [40]. Acute ingestion of antimony salts primarily affects the gastrointestinal tract. Toxicity manifests as nausea, vomiting, watery diarrhea, abdominal pain, melena, and hematemesis and may lead to volume depletion and hypovolemic shock [41]. One or two grains of tartar emetic were sufficient to cause death in a child and adult, respectively [44]. Seventy people became ill after ingesting lemonade contaminated with antimony trioxide [42]. Patients presented with abdominal pain, nausea, and vomiting; the majority recovered within 3 h of ingestion.

Chronic oral exposure to trivalent and pentavalent antimony compounds is speculated to result in cardiovascular and gastrointestinal toxicity. A causal relationship to antimony could not be definitively established due to the presence of other agents [43, 44]. Cardiovascular effects include elevated blood pressure and electrocardiogram abnormalities, including T wave changes with prominent U waves and QT interval prolongation [44]. Stokes-Adams syndrome, responsive to atropine, has been described with acute and long-term administration (orally or intravenously) of antimony potassium tartrate [3]. Chronic antimony exposure in itself does not appear to be associated with increased risk of ischemic heart disease [7].

Inhalational antimony exposure is irritating to the mucous membranes. It is associated with pharyngitis, conjunctivitis, rhinitis, and epistaxis. Although nasal septal perforation was observed among smelter workers, this finding was attributed to concomitant arsenic exposure [1].

Studies of pulmonary antimony toxicity have been plagued by the presence of confounding

Fig. 1 Antimony Dermatitis

exposures, including arsenic oxide, iron oxide, hydrogen sulfide, and particulates [1, 45, 46]. Chronic occupational exposure to airborne antimony is associated with development of pneumoconiosis [47]. Radiographic studies performed on smelter workers demonstrated a 15.7% prevalence of pneumoconiosis, with associated decreased FEV and FVC [48]. Elevated antimony concentrations were found in the lungs of smelter workers 20 years after retirement. These concentrations seemed to increase with duration of exposure [49]. Other respiratory findings include chronic bronchitis, chronic emphysema, pleural adhesions, and respiratory irritation (including coughing, wheezing, and upper airway inflammation) [7, 46].

Antimony dermatitis is a pustular eruption of the trunk and limbs near sweat and sebaceous glands [50, 51] (Fig. 1). It is more commonly noted in workers exposed to high temperatures or in hot weather. The dermatitis improves within 2 weeks after transfer to a cooler environment.

Commonly reported adverse effects associated with sodium stibogluconate and meglumine antimoniate treatments are musculoskeletal pain, nausea, vomiting, diarrhea, abdominal pain, headache, anorexia, fatigue, fever, erythema, and urticaria [52]. A high incidence of severe cutaneous reactions in patients treated with meglumine

antimoniate 20 mg/kg/day was subsequently determined to be due to high concentrations of other heavy metals in the particular drug lot, including trivalent antimony, lead, cadmium, and arsenic [53]. However, all skin reactions noted in this cohort occurred in historical controls, albeit at a lesser frequency.

The most concerning toxicity associated with pentavalent antimonial therapy is cardiotoxicity, which may occur at the recommended dose of 20 mg/kg/day [4]. Studies in India and Africa have reported frequent adverse cardiac events in patients using pentavalent antimonials, including ventricular tachycardia, torsade de pointes, and sudden cardiac death [54]. Electrocardiographic manifestations of parenteral antimony cardiotoxicity include ventricular premature contractions, first-degree atrioventricular block, T wave and ST-T changes, and prolonged QTc interval [4, 55–57]. These changes are reversible with cessation of treatment. In one cluster of cardiotoxicity and death, QTc prolongation was followed by ventricular ectopy and then malignant ventricular dysrhythmias, including torsade de pointes and ventricular fibrillation [58]. The cluster was attributed to incorrect formulation, with resultant unexpected increase in osmolarity. Another cluster of cardiotoxicity occurred after introduction of a new generic formulation of sodium stibogluconate [59]. Eight of 23 patients treated with the new generic product died, with five deaths secondary to drug cardiotoxicity.

A retrospective analysis of returned travelers with New World cutaneous or mucosal leishmaniasis who received intravenous sodium stibogluconate (pentavalent) for more than 21 days demonstrated progressive QTc prolongation from 389 ± 3.1 to 404 ± 2.9 msec [60]. During the third week of treatment, 10% of patients reached the threshold for potential cardiac toxicity, defined as a QTc prolonged >50 msec above baseline or an absolute value >450 msec. An 81-year-old male with hypertension, cardiomegaly, and a baseline QTc of 429 msec developed short runs of ventricular tachycardia on day 9. This patient, on a thiazide diuretic concurrently with sodium stibogluconate therapy, had a serum potassium of 2.7 mmol/L and a QTc of

567 msec. In contrast, cardiotoxicity was not observed among 96 US military personnel with cutaneous leishmaniasis treated with Pentostam® (sodium stibogluconate) [61]. These differences have been attributed to the greater systemic morbidity of visceral versus cutaneous leishmaniasis, different drug formulations, and different cardiovascular risk profiles of studied populations. Another study noted the development of arrhythmia in a patient without any apparent comorbidity, requiring cessation of treatment.

Hepatobiliary, hematologic, and renal toxicity have been noted with pentavalent antimonial therapy. In one study, increases in serum AST or ALT above the upper limit of normal were noted in 85% of patients, and increases greater than three times the upper limit of normal were noted in 33% [60]. Peak transaminase levels occurred on day 12. No patients developed clinical signs of hepatitis, including right upper quadrant tenderness, hepatic enlargement, or jaundice. Elevated amylase, with and without evidence of clinical pancreatitis, has been observed [60, 62–64]. Sixteen of 17 patients treated with sodium stibogluconate manifested elevated amylase and lipase; 12 patients developed clinical symptoms consistent with pancreatitis [62]. Elevated amylase without clinical pancreatitis was noted in 67% of patients, with an increase greater than three times the upper limit of normal occurring in 19% of patients [60]. Although amylase elevations are typically asymptomatic, deaths due to acute pancreatitis have been reported [63].

Diverse hematologic abnormalities have been observed. Acute anemia due to erythroid precursor bone marrow toxicity was noted in a 6-year-old male treated with sodium stibogluconate for visceral leishmaniasis [65]. Over the course of treatment, the hemoglobin decreased from 7.2 to 3.5 g/dL. Within 4 days of treatment cessation, the patient's hemoglobin had increased to 5 g/dL with a corrected reticulocyte count of 10%. Parenteral sodium stibogluconate administration was associated with significant decreases in lymphocyte and platelet counts [66, 67]. Mean decrease in platelet count by day 4 was 31,000 [66]. Antimony trioxide nanoparticles demonstrated *in vitro* toxicity to hematopoietic progenitor cells,

specifically impairing the proliferation of erythroid progenitors [68]. No effect was noted on erythroid differentiation or on granulocyte-monocyte precursors.

Acute renal tubular acidosis and acute tubular necrosis have rarely been reported [52, 69, 70]. Other observed laboratory abnormalities include elevated creatine phosphokinase and alkaline phosphatase [71]. A 19-year-old male who intentionally ingested 500 mg of tartar emetic as therapy for alcohol dependence developed hyperkalemia (6.1 mEq/L) without ECG changes [72]. All abnormalities were transient and returned to normal after completion of treatment.

In summary, analogous to arsenic, antimony effects diverse organ systems, resulting in cardiovascular, pulmonary, gastrointestinal, dermatologic, renal, and hepatobiliary toxicity. Cardiac dysrhythmias and sudden cardiac death, related to progressive QTc prolongation, remain the greatest concern in the evaluation and management of antimony toxicity.

Diagnosis

Antimony toxicity should be considered in patients presenting with gastrointestinal or pulmonary symptoms or electrocardiogram changes, who are being treated for leishmaniasis or work with antimony compounds. Consider the concomitant presence of other heavy metals. The diagnosis of antimony poisoning is made by measuring antimony concentrations via atomic absorption spectroscopy in blood, urine, or both [73]. The normal serum antimony concentration is 3 mcg/L, while the normal 24-h collection urine concentration is 0.8 mcg/L [74]. In 2009, the US Centers for Disease Control and Prevention (CDC) investigated a possible outbreak of antimony toxicity among Florida firefighters, presumed due to the fire retardant in the outer protective clothing [75, 76]. The index case complained of neurological symptoms and was noted to have elevated antimony on hair sample analysis. Extensive evaluation revealed no evidence of elevated urinary antimony levels in firefighters wearing antimony-containing fabrics. The CDC specifically

Fig. 2 Treatment Algorithm for Presumptive or Known Antimony Toxicity

cautioned about the use of non-validated methods, including hair testing, to determine antimony toxicity.

Treatment

After antimony ingestion, the majority of patients will develop emesis. The ability of activated charcoal to reduce antimony absorption from the gastrointestinal tract in acute antimony poisoning has not been studied (see Fig. 2). Theoretically, activated charcoal may be efficacious in reducing absorption if it is administered within the first 1–2 h after oral ingestion (Level III) [77]. However, there are no data indicating that administration of activated charcoal changes patient outcome. Whole-bowel irrigation may have a role in management, analogous to arsenic poisoning (Level III) [78]. Aggressive intravenous administration of crystalloids with appropriate cardiovascular

monitoring may be necessary to replace volume loss. Vasopressors and/or inotropes may be necessary to treat shock not responsive to fluid volume replacement. The treatment of shock is discussed in detail elsewhere (► Chap. 14, “The Assessment and Management of Hypotension and Shock in the Poisoned Patient”). Because QTc prolongation may lead to the development of torsade de pointes, continuous cardiac monitoring should be implemented if there are electrocardiogram changes or other significant manifestations of antimony poisoning. The treatment of this dysrhythmia is outlined in ► Chap. 22, “Toxicant-Induced Torsade de Pointes.” In one case report, N-acetylcysteine was used as a glutathione precursor to facilitate the conjugation and enterohepatic excretion of antimony [79].

Box 1: Indications for ICU Admissions: Antimony

1. Symptomatic patients after acute oral exposure (Level III)

2. Evidence of severe toxicity with hemodynamic or respiratory compromise (Level III)
3. Evidence of ECG abnormalities (including QT prolongation*) or dysrhythmias (Level III)
4. Evidence of acute kidney injury, pancreatitis, or hepatic injury (Level III)
5. Known or presumptive stibine exposure (Level III)

*Otherwise stable patients with isolated QT prolongation may alternatively be admitted to a telemetry bed.

In an attempt to enhance antimony elimination, the use of chelating agents has been proposed. Dimercaprol (British anti-lewisite [BAL]) was reported to decrease the toxicity of antimony potassium tartrate in rabbits and to be effective in ameliorating the toxicity and adverse reactions during treatment with other trivalent antimonial drugs [80, 81]. Administration of dimercaprol 30 mg/kg IM 1-h postexposure followed by 15 mg/kg at 6, 24, and 48 h increased the LD50 of intramuscular antimony from 90 to 160 mg/kg [80]. In another study, dimercaprol 10–15 mg/kg administered 4 times at 4-h intervals resulted in a 50% reduction in mortality [81]. 2,3-Dimercaptosuccinic acid (DMSA, succimer) and 2,3-dimercaptopropane-1-sulfonate (DMPS), two derivatives of dimercaprol, have been shown to decrease mortality in mice given antimony tartrate in a dose twice the median lethal dose. Intraperitoneal DMSA administered 20 min after administration of antimony potassium tartrate 120 mg/kg resulted in the survival of 28 of 30 mice [82]. Nineteen of 30 mice receiving intraperitoneal DMPS survived; D-penicillamine was less effective than DMPS, while dimercaprol did not decrease mortality in this model.

Human chelation studies are limited. In four patients who were accidentally overdosed with antimony tartrate, intramuscular dimercaprol 200–600 mg per day did not seem to change the course of their toxicity [40]. DMSA administration 72-h postexposure did not increase antimony excretion in a patient who accidentally received an overdose with sodium stibogluconate [83]. However, the authors noted that most of

the antimony was eliminated in the first few hours. A 34-year-old male presented to the emergency department with abdominal pain and vomiting after ingesting tartar emetic [79]. Due to ongoing emesis, the patient was initially treated with intramuscular dimercaprol. This was discontinued after the third dose due to chest pain, tachycardia, hypertension, and nonspecific ECG changes. The patient was subsequently switched to DMSA, but this too was discontinued due to the development of transaminitis, subsequently attributed to the antimony.

In the absence of more robust data, DMSA (10 mg/kg orally every 8 h for 5 days followed by 10 mg/kg every 12 h for 14 days) may be considered in the management of trivalent antimony compound poisoning (Level III evidence). DMSA should be administered as early as possible after toxic exposure. Dimercaprol may be considered in patients with intractable emesis unable to tolerate oral DMSA. In the absence of specific dosing data, dimercaprol may be administered at doses used for arsenic poisoning (3 mg/kg every 4 h for 48 h, followed by twice daily for 7–10 days; alternate regimen 5 mg/kg every 4–6 h for 24 h, with a tapering dose and duration based upon patient symptomatology). Based upon animal data, penicillamine (250 mg in adults and 20–30 mg/kg in children four times a day) may also serve as an alternative to DMSA, although DMSA is considered the most effective chelating agent (Level III evidence) [82]. The current available data do not support chelation for pentavalent antimony toxicity. The duration of therapy should be guided by the clinical response.

Box 2: Criteria for ICU Discharge

The patient may be discharged from the ICU when acute symptomatology, evidence of end-organ or hemodynamic compromise, and ECG abnormalities resolve (Level III recommendation).

Stibine

Stibine (SbH_3 , hydrogen antimonide, antimony hydride) is a colorless gas formed when antimony

alloys are treated with acids and subjected to electrolytic action, such as during the charging of certain lead-containing batteries. In 1990, stibine was implicated as the cause of sudden infant death syndrome (SIDS), due to the purported actions of the fungus *Scopulariopsis brevicaulis* on fire retardant PVC cot mattress covers [83]. In vitro studies demonstrated the generation of stibine, phosphine, and hydrides of antimony oxides, which were speculated to cause antimony toxicity and subsequent sudden infant death. Further study demonstrated that antimony volatilization did not occur unless cot mattress PVC was heated to 80–100 °C and that antimony trioxide in cot mattress PVC was not bioavailable [84]. Subsequently, urine antimony concentrations in SIDS infants were found to be similar to control and healthy infants, refuting this theory [85]. Detection of antimony in hair of healthy babies further suggested no link between antimony and SIDS [41].

Clinical Presentation and Life-Threatening Effects

In animals, stibine was shown to be lethal and to cause pulmonary edema and hemolysis in a dose-dependent manner, analogous to arsine gas [86]. Several cases of poisoning from a mixture of gases including stibine (others being arsine and hydrogen sulfide) have been reported [87]. The hallmark of arsine poisoning is intravascular hemolysis secondary to binding of arsine with oxidized hemoglobin. In a case report of acute arsine poisoning, antimony was detected in the urine of one patient, suggesting the co-formation of stibine through the same mechanism as arsine formation [87]. Although studies of pesticide workers exposed to phosphine demonstrated decreased RBC and pseudocholinesterase activity, suggesting a possible mechanism for stibine toxicity [88], subsequent studies found this to be incorrect [89].

Clinical features of stibine toxicity include headache, nausea, weakness, abdominal and back pain, and severe hemolysis.

Treatment

The treatment for acute stibine poisoning is supportive (See Fig. 2). Fluid hydration and maintenance of urine output are important to prevent renal injury secondary to hemolysis. Erythrocyte transfusions may be required if the hemolytic anemia is severe or if the patient has compromised cardiopulmonary function. In the case of arsine, early exchange transfusion has been recommended in patients with evidence of severe toxicity due to the difficulty in detecting acute hemolysis (Level III recommendation) [90]. It is unknown whether chelating agents have any role in the management of stibine poisoning.

Box 3: Key Points for Antimony Poisoning

1. Antimony toxicity is analogous to that of arsenic.
2. Acute ingestion is associated with GI toxicity, including hematemesis and shock.
3. Chronic inhalational exposure is associated with pneumoconiosis.
4. The most concerning toxicity associated with pentavalent antimonial therapy is cardiotoxicity.
5. Stibine is associated with acute lung injury and hemolysis.
6. Antimony toxicity should be considered in patients presenting with gastrointestinal or pulmonary symptoms or electrocardiogram changes, who are being treated for leishmaniasis or work with antimony compounds.
7. Antimony toxicity should not be diagnosed based upon non-validated techniques, including hair analysis.
8. In the absence of more robust data, DMSA may be considered in the management of trivalent antimony compound poisoning (Level III).
9. Penicillamine is an alternative to DMSA, although DMSA is considered the most effective agent (Level III).
10. Current data do not support chelation for pentavalent antimony toxicity (Level III).
11. Early exchange transfusion may be considered for acute stibine exposure (Level III).

Nickel

Nickel is the fifth most common metal in the Earth's crust and is distributed widely in soils and sediment. It is used in many different industries, including mining, petroleum, electroplating, and ceramics and is used as yellow pigment in paint. Two general types of nickel ore exist: magmatic sulfide ores, which are mined underground, and lateritic hydrous nickel silicates or garnierites, which are surface mined [91, 92]. Nickel carbonyl is a volatile liquid nickel compound formed from the reaction of carbon monoxide and nickel compounds. It is often described as having a sooty or musty odor.

Biochemistry and Clinical Pharmacology

Nickel's physical properties allow for its broad use in industry. Pure nickel is a hard, silvery-white metal that is combined with other metals to form alloys. It is a hard, yet malleable, metal that is relatively resistant to corrosion. Nickel and its compounds have no characteristic odor or taste. The most familiar nickel ferrous alloys are stainless steel and coinage metal. Nickel may be found in the metallic, inorganic, and organic forms. Although nickel can exist in oxidation states -1 , 0 , $+2$, $+3$, and $+4$, its only medically important oxidation state is $+2$.

Nickel has typical metallic properties. It also is ferromagnetic and a good conductor of heat and electricity. Nickel is positioned after hydrogen in the electrochemical series and slowly displaces hydrogen ions from dilute hydrochloric and sulfuric acids. It reacts more rapidly with nitric acid. Nickel is highly resistant to attack by strong alkali [93]. Nickel ($+2$) forms an extensive series of compounds and is the only important oxidation state in aqueous systems. Other oxidation states occur in special complexes and oxides. In alkaline solutions, nickel ($+2$) hydroxide can be oxidized to a hydrated nickel ($+4$) oxide, a reaction used in the Edison storage battery.

In aqueous solutions, nickel occurs as the octahedral hexahydrate ion $[\text{Ni}(\text{H}_2\text{O})_6]$, which is poorly absorbed by most living organisms [94, 95]. Nickel subsulfide is formed during the roasting and smelting of nickel ore and may be shipped as the matte for further processing, but it does not have any other significant commercial uses [96]. Data on the chemical properties of nickel and some important nickel compounds are presented in Table 2.

Nickel may be absorbed via inhalation or ingestion. Absorption by the respiratory route with secondary gastrointestinal absorption (insoluble and soluble) is the major pathway of exposure during occupational exposures. Similar to many inhaled particles, significant quantities may be swallowed after mucociliary clearance from the respiratory tract. The soluble nickel ion (Ni^{2+}) may be absorbed through the gastrointestinal tract, while less soluble compounds may be phagocytized in the lung. Percutaneous absorption is negligible for most nickel compounds, but for some forms, such as nickel chloride and nickel sulfate, 77% of an applied dose may be absorbed [96].

Due to high volatility and high lipid solubility, the organonickel compounds, such as nickel carbonyl, have the greatest propensity for absorption. It has been reported that 35% of inhaled nickel is absorbed into the blood [97–99]. Ingestion of nickel results in absorption of variable amounts. Bioavailability of nickel is altered by the presence of food in the gastrointestinal tract [97]. When nickel sulfate is given with water, 27% is absorbed, whereas only 0.75% is absorbed with food. After absorption, nickel enters the vascular compartment, where it is bound principally to albumin (34%) and nickeloplasmin (26%), with none as an unbound ultrafiltrable fraction [100]. Nickel carbonyl is distributed into the central nervous system to a greater extent than its other forms.

Metallic nickel is not metabolized. Nickel carbonyl is oxidized to nickel and carbon monoxide [100]. However, in a study of five subjects with nickel carbonyl poisoning, none developed elevated carboxyhemoglobin levels [101]. This finding was confirmed in a series of 25 cases [102, 103]. Biomonitoring after nickel carbonyl

Table 2 Physical and chemical properties of nickel and selected compounds^a

Property	Nickel	Nickel oxide	Nickel sulfate	Nickel chloride
Molecular weight	58.69	74.69	154.75	129.60

From ATSDR: Toxicological Profile for Nickel. Report TP-92/14. Atlanta, GA, US Public Health Service, Agency for Toxic Substances and Disease Registry, 2005.

^aAll information obtained from HSDB 1996 except where noted

^bIshimatsu et al. [130]

exposure should focus on the detection of nickel in blood or urine samples [104]. In a rat model, 35% of nickel carbonyl was eliminated via the kidney [101]. Parenteral nickel is eliminated almost exclusively in the urine, where it is cleared rapidly from the body [105]. Nonabsorbed nickel (approximately 90%) is eliminated in the feces [104].

Pathophysiology of Toxic Effects

Nickel's toxicity may be related to its interference with physiologic processes involving other metal cations, such as manganese, zinc, calcium, and magnesium. The pathophysiology of nickel carbonyl-induced acute lung injury is complex. Nickel ions generate reactive oxygen species, including

superoxide anion radicals [106]. Animal studies suggest a complex pathway leading to acute lung injury, including generation of reactive oxidative species, subsequent lipid peroxidation generating malondialdehyde, which in turn causes DNA damage [107]. Altered expression of cell cycle proteins Chk1 and Cdc2 was also noted, suggesting a mechanism of cell cycle arrest and apoptosis.

Clinical Presentation and Life-Threatening Complications

For the most part, nickel exposure is self-limited and benign. Allergic contact dermatitis to nickel is common, estimated to affect 10% of the human population [108]. More significant allergic reactions, including reactive airway disease, have been reported [109, 110].

Inhalation of nickel alloys or dust is associated with upper airway and pulmonary irritation, reactive airway disease, pneumoconiosis, and pulmonary fibrosis. Analogous to metal fume fever, acute lung injury in a welder has been reported after exposure to nickel fumes [111, 112]. Ingestion is associated with systemic toxicity, particularly involving the central nervous system. Exposure to nickel was associated with generalized tonic-clonic seizures and nonconvulsant focal status epilepticus in two patients working in the same shop [113].

Nephrotoxic effects, such as renal edema with hyperemia and parenchymatous degeneration, have been reported in 32 cases of electroplaters who accidentally drank water contaminated with nickel sulfate and nickel chloride [114]. The workers developed nonspecific signs and symptoms (e.g., nausea, vomiting, abdominal discomfort, diarrhea, giddiness, lassitude, headache, cough, shortness of breath) that were transient in most but persisted 1–2 days in seven cases. Ten workers with initial urine nickel concentrations greater than 0.8 mg/g of creatinine were hospitalized and treated with intravenous fluids. This treatment resulted in a mean elimination half-life for serum nickel of 27 ± 7 h, which was significantly shorter than the mean half-life of 60 ± 11 h in 11 subjects who did not receive intravenous

fluids. All subjects recovered rapidly, without evident sequelae, and returned to work by the 8th day after exposure.

Box 4: Indications for ICU Admission: Nickel

1. Known or suspected exposure to nickel carbonyl, even if asymptomatic (Level III)
2. Evidence of hemodynamic instability or respiratory compromise (Level III)
3. Significant inhalational exposure of nickel fumes (Level III)
4. New-onset seizures after nickel exposure (Level III)
5. 8-h urinary nickel concentration greater than 50 mcg/dL (Level III)

Few nickel exposures result in a critical care admission. The exception is nickel carbonyl, which may cause multisystem toxicity, particularly involving the pulmonary system, within hours after significant inhalational exposure [115–117]. The severity of toxicity of nickel carbonyl has been compared with hydrogen cyanide [117]. In one study, 40% of patients developed symptoms within 1 h of exposure, while 20% did not manifest symptoms for up to 1 week from exposure [118]. Acute lung injury is typically delayed, occurring after a prodrome of flu-like symptoms, but may occur immediately after exposure. Radiographic pneumonitis may persist for 4 weeks [103]. Transient pulmonary infiltrates and eosinophilia (Löffler's syndrome) have been reported after low-dose inhalational exposure to nickel carbonyl [94]. Cardiac manifestations of nickel carbonyl exposure may include myocarditis and electrocardiographic abnormalities, including QT prolongation and heart block [118]. Deaths are frequently due to acute lung injury or cerebral edema [103, 114, 115]. In survivors, a prolonged neurasthenic syndrome has been reported, lasting several months in some cases [118].

Treatment

The most important intervention after nickel exposure is the interruption of any potential ongoing absorption (see Fig. 3). Removal from

Fig. 3 Treatment Algorithm for Presumptive or Known Nickel Toxicity

exposure and decontamination is of primary importance. With nickel or nickel carbonyl poisoning, it is important to remove any contaminated clothing. In a descriptive study of seven patients presenting 72 h after nickel carbonyl exposure, four patients were admitted to the ICU; all three patients requiring endotracheal intubation died [119]. Surviving patients were asymptomatic on follow-up 6 months later.

Box 5: Criteria for ICU Discharge

1. The patient may be discharged from the ICU when asymptomatic for 24 h or when all evidence of toxicity has resolved and urinary nickel levels are less than 10 mcg/dL (Level III).

Few specific therapeutic measures are available. Most traditional chelating agents are not of

value. Sodium diethyldithiocarbamate (DDC) and disulfiram (US trade name Antabuse) appear effective as nickel chelators, with DDC being the preferred agent (Level III evidence). In a rat model, DDC given parenterally at a dose of 50–100 mg/kg immediately after nickel carbonyl administration resulted in reduction of mortality from 73% to 8% [120]. In another animal study, mice were given 50–100 mg/kg of DDC, which was protective when given 8 h after exposure. The efficacy declined at 24 h. The 100-mg/kg dose was more efficacious than a lower dose [121].

Disulfiram (bis (dimethylthiocarbamoyl) disulfide) is metabolized to two molecules of DDC. Given at a dose of 1000 mg/kg to rats, disulfiram offered complete protection against nickel carbonyl-induced toxicity when administered after exposure; however, 500 mg/kg offered no protection [122]. Doses greater than 1500 mg/kg

Table 3 Diethyldithiocarbamate (DDC) and disulfiram dosing regimens for acute nickel carbonyl poisoning (Level III)

Urinary nickel concentration	Anticipated clinical severity	Chelating agent	Suggested dosing regimen
<10 mcg/dL	Mild	None	Treat as moderate if severe symptoms develop
10–50 mcg/dL	Moderate	DDC	Day 1: 35–45 mg/kg orally in divided doses to decrease nausea. Day 2 and beyond. ¹ Give 400 mg every 8 h until symptom free and urinary nickel concentration <10 mcg/dL
>50 mcg/dL	Severe	DDC	Initial dose 25 mg/kg IV. ² Severe cases may require 100 mg/kg in the first 24 h. Additional dosing based upon clinical severity
Unknown level	Concern for moderate to severe exposure	DDC	Administer 2 mg orally in divided doses. Additional dosing based upon clinical severity and urinary levels
DDC unavailable	Evidence of toxicity	Disulfiram	750 mg orally every 8 h for 24 h, then 250 mg every 8 h until symptom free

Refs. [118, 119, 125, 126]

1. Suggested dosage schedule for an approximately 70-kg patient is:

- (a) Dose 1: 1000 mg (5×200 -mg capsules) in first hour
- (b) Dose 2: 800 mg (4×200 -mg capsules) from hour 1 to 4
- (c) Dose 3: 600 mg (3×200 -mg capsules) from hour 4 to 8
- (d) Dose 4: 400 mg (2×200 -mg capsules) from hour 8 to 16

2. DDC solution can be prepared by adding 10 mL of sterile solution of phosphate buffer (500 mg per NaH_2PO_4 per 100 mL) to 1-g powdered sterile DDC

seemed to enhance mortality. In one case report, disulfiram was administered after inhalational exposure to nickel carbonyl for the first 2 days until sodium DDC was obtained. The patient gradually improved over 10 days [117]. Because of the use of DDC, the efficacy of disulfiram could not be determined.

There are no adequately controlled clinical studies of the use of disulfiram or DDC in acute nickel carbonyl poisoning. Disulfiram or DDC may be considered as a possible therapeutic intervention in seriously ill patients (Table 3). DDC treatment guidelines are listed in Table 3 (Level III) [116, 123]. If DDC is unavailable, disulfiram may be used as an alternative (Level III) [124–126]. Current dosing strategies are based upon an 8-h urinary nickel level collected immediately after exposure [125]. Animal studies suggest that treatment is most effective when administered as soon as possible after exposure, leading to the recommendation that treatment should not be delayed while awaiting diagnostic data [120]. In reconciling these conflicting approaches, it would appear reasonable to delay treatment pending urinary nickel study results in

mildly and moderately symptomatic patients and initiate treatment immediately in severely symptomatic or critically ill patients (Level III recommendation). Nausea is common with DDC therapy and should be managed expectantly. Patients receiving treatment with DDC or disulfiram should be advised to avoid ethanol for at least 1 week after treatment. Although nickel carbonyl may be oxidized to carbon monoxide, no evidence of carbon monoxide poisoning has been noted [101–103]. The utility of routine carbon monoxide screening in nickel carbonyl poisoning remains unclear (Level III).

Box 6: Key Points in Nickel Exposure

1. For the most part, nickel exposure is self-limited and benign.
2. Exposure to nickel fumes may cause acute lung injury analogous to metal fume fever.
3. Nickel carbonyl exposure is associated with delayed pulmonary edema.
4. Sodium diethyldithiocarbamate (DDC) and disulfiram appear effective as nickel chelators, with DDC being the preferred agent (Level III).

5. Chelation therapy should not be delayed in symptomatic patients with suspected nickel carbonyl exposure (Level III).
6. Patients receiving treatment with DDC or disulfiram should be advised to avoid ethanol for at least 1 week after treatment (Level III).
7. Although nickel carbonyl may be oxidized to carbon monoxide, no evidence of carbon monoxide poisoning has been observed (Level III).

Arsenic has captured the attention of the medical community for more than two millennia as a cause of disease and as a cure. Hippocrates and other ancient Greek physicians described the use of arsenic sulfides such as realgar (As_2S_2) or orpiment (As_2S_3) as a topical treatment for ulcers. During the first millennium AD, the roasting of realgar led to the discovery of the so-called white arsenic, or arsenic trioxide. Odorless, tasteless, and soluble in solution, it became a tool of deliberate poisoning and gained particular notoriety as a homicidal agent in Europe in the fifteenth through seventeenth centuries. In the late eighteenth century, Fowler [1] described the medical use of a 1% solution of potassium arsenite as an oral treatment for fever and chorea. Known as *liquor arsenicalis* or *Fowler's solution*, it was used extensively until the mid-twentieth century as a remedy for asthma and psoriasis. In the nineteenth century, arsenic compounds were used widely in commerce as pigments (e.g., copper arsenite or “Scheele’s green”). Several arsenic compounds were used through most of the twentieth century as pesticides (e.g., lead arsenate, calcium arsenate) or herbicides (e.g., sodium arsenite). Until recently, the wood preservative chromated copper arsenate represented the largest commercial use of arsenic, although use in new residential products has been discontinued. Ammoniacal copper zinc arsenate is still used as a wood preservative in limited industrial applications. Organic arsenic antibiotics were used extensively in humans in the first half of the twentieth century in the treatment of protozoan

and spirochetal diseases, and until recently phenylarsenic agents were used as feed additives for poultry and swine. The link between environmental and occupational arsenic exposure and chronic nonmalignant and malignant disease became well established in the latter half of the twentieth century, leading to a reduction in many commercial applications and recent regulatory efforts to reduce permissible exposure levels in drinking water, where arsenic of geologic origin may occur as a natural contaminant.

Semiconductor manufacturing is one industrial sector that has seen expanded the use of arsenic-containing compounds in recent decades. Hydride forms of arsenic, such as arsine gas, have been used as a source of arsenic dopants for silicon chips, and gallium arsenide has been used increasingly as a substrate for semiconductors. Inorganic arsenic has reemerged as a medicinal agent for the treatment of acute promyelocytic leukemia, and its potential utility in the therapy of other selected malignancies is under investigation. Arsenic trioxide was approved by the U.S. Food and Drug Administration as an orphan drug for the secondary treatment of acute promyelocytic leukemia in September 2000.

Biochemistry

Arsenic

Elemental arsenic (atomic weight 74.92) is a naturally occurring silver-gray solid metalloid. The elemental (zero valence) form, which rarely exists in nature and has low solubility, is seldom a cause of human toxicity. Rather, human exposure may occur predominantly to a variety of inorganic arsenic salts and natural and synthetic organoarsenic compounds, whose toxicity varies considerably depending on the molecular form, valence state, solubility, and exposure circumstances.

The principal inorganic forms of arsenic of toxicologic concern are the soluble crystalline solids and salts of trivalent (As^{+3}) arsenite and pentavalent (As^{+5}) arsenate. Trivalent arsenic compounds generally have greater acute toxicity

than the pentavalent forms, but *in vivo* interconversion occurs, and the two forms are capable of producing a similar pattern of acute and chronic intoxication. In the approach to a poisoned patient, there is seldom a clinical reason to distinguish whether the exposure has been to arsenite or arsenate. Arsenic trioxide (As_2O_3) is a commercially important crystalline solid that usually is produced from the smelting of copper or lead ores containing arsenic sulfides, such as arsenopyrite (FeAsS). Arsenic trioxide is moderately soluble in water (37 g/L at 20 °C), and arsenic pentoxide (As_2O_5) is very soluble in water (1500 g/L at 16 °C) [2]. Commonly encountered soluble arsenic salts include sodium arsenite (NaAsO_2) and sodium arsenate (Na_2HAsO_4). Inorganic arsenic of geologic origin occurs in natural waters, particularly groundwater in the vicinity of arsenic-bearing soils or sediments, where local redox conditions influence the relative preponderance of arsenite or arsenate species. Inorganic compounds of low solubility seldom have been associated with overt acute toxicity because of poor absorption and limited systemic distribution. These compounds include the former pesticide and herbicide calcium arsenate, which still may be encountered as a natural contaminant of some coal fly ash, and gallium arsenide (GaAs), which is used in semiconductors.

Pharmacokinetics and Metabolism of Arsenic Compounds

Volume of Distribution

In humans given an intravenous bolus of radio-labeled arsenite in a clinical study, the initial volume of distribution was calculated to be 0.2 L/kg [3]. Because initial plasma clearance was rapid (half-life approximately 0.45 h), however, the volume of distribution after 2–3 h appeared to increase to approximately 6 L/kg. Pharmacokinetic analysis of plasma arsenic in ten chemotherapy patients receiving an intravenous dose of As_2O_3 (0.15 mg/kg) over 2 h observed a volume of distribution of 15.2 ± 6.7 L/kg at the terminal elimination

(continued)

phase during the first day of therapy [4]. However, since calculations were based on arsenic concentration in plasma, and not the higher values usually found in whole blood [5], the volume of distribution reported may have overestimated the actual extravascular distribution.

Protein Binding

At low background levels, arsenic in the blood follows a red blood cell-to-plasma ratio of approximately 1:1, but this ratio increases at higher levels of arsenic exposure in humans and animals [6]. In two patients receiving arsenic chemotherapy, the concentration of total arsenic in whole blood (approximately 100–200 µg/L) was about two- to threefold higher than total arsenic in plasma [5]. Within the plasma of these patients, approximately two-thirds of the arsenic appears to be protein bound [7]. Studies in patients undergoing peritoneal dialysis indicated that approximately 5% to 6% of the inorganic arsenic in serum is bound to protein, predominantly to transferrin [8]. The total serum arsenic in these patients (mean 4.7 µg/L) was higher than that of a reference population (0.96 ± 1.52 µg/L) [9] and was much lower than levels encountered in the early phases of acute arsenic intoxication.

Mechanisms of Clearance

In humans, inorganic arsenic and its methylated metabolites are excreted overwhelmingly (>95%) via the urine. Minor to trace amounts are eliminated via the feces, sweat, skin, and appendages (hair and nails) [3, 10, 11]. In a study involving ingestion of radiolabeled arsenate, elimination was characterized by a three-component exponential function, with 66% of the arsenic eliminated with a half-life of 2.1 days, 30% with a half-life of 9.5 days, and 4% with a half-life of 38.4 days [11]. In other human ingestion studies, the half-life of urinary arsenic excretion after ingestion of 500–1000 µg arsenite was 2–3 days [12, 13]. The elimination of arsenic is prolonged, however, after high-dose exposure [6]. In

acutely poisoned humans, elevated urinary arsenic levels still may be detectable several weeks after the termination of exposure [14–16]. Some data suggest that arsenic may undergo enterohepatic or enteroenteric circulation in humans, but the extent of this process has not been well characterized.

Active Metabolites

Inorganic arsenic undergoes *in vivo* biomethylation to form monomethylated and dimethylated metabolites (Fig. 1). The principal metabolites are the pentavalent species, monomethylarsonic acid (MMA^{V}) and dimethylarsinic acid (DMA^{V}), which are less acutely toxic than inorganic arsenic by an order of magnitude [2]. After chronic low-dose exposure to inorganic arsenic, the methylated metabolites account for approximately 70–90% of arsenic excreted in the urine [17]. The biomethylation process also produces small amounts of the trivalent methylated species, monomethylarsonous acid (MMA^{III}) and dimethylarsinous acid (DMA^{III}), however, which have been found to be more acutely toxic than inorganic arsenic (arsenate or arsenite) [18–20]. Methylation cannot be viewed exclusively as a detoxification process. Genetic polymorphisms resulting in decreased methylation efficiency and a relative increase in the ratio of MMA to DMA in urine have been associated with an increased risk of chronic arsenic-related health impacts [21]. Recent human studies have found that thioarsenite compounds including dimethylmonothioarsinic acid (DMMTA^{V}) occur *in vivo* as minor metabolites that may also contribute to arsenic toxicity [22, 23].

Methods to Enhance Clearance

Because arsenic is excreted via the kidney, intravenous hydration and other supportive care that maintain adequate urine output help to optimize clearance. Chelation may accelerate arsenic excretion. Arsenic is cleared rapidly from the blood, and hemodialysis contributes little to clearance in patients with intact renal function.

Fig. 1 Known pathways of arsenic metabolism in vertebrates. Abbreviations: *GSH* glutathione, *GST-omega* glutathione S-transferase omega, *SAHC* S-adenosylhomocysteine, *SAM* S-adenosylmethionine. Note the need to consider six

arsenic forms when exposure may be to arsenate alone. Reproduced from https://openi.nlm.nih.gov/detailedresult.php?img=PMC2137106_ehp0115-001770f1&req=4 under a Public Domain license

Noteworthy organoarsenicals include synthetic and natural products. In humans, inorganic arsenate or arsenite undergoes *in vivo* biomethylation in certain tissues to monomethyl and dimethyl forms that ultimately are excreted in the urine. The main biomethylation products are the pentavalent species monomethylarsonic acid (MMA^V) and dimethylarsinic acid (DMA^V), which have lower acute toxicity than inorganic arsenic. More recent studies have shown that trivalent methylated forms, monomethylarsonous acid (MMA^{III}) and dimethylarsinous acid (DMA^{III}), which exist in small but stable amounts *in vivo*, have acute toxicities greater than the toxicity of arsenite. Synthetic DMA^V (also known as *cacodylic acid*) or its sodium salt were formerly used as agricultural chemicals, and it is still used as a laboratory buffer. The sodium salt of MMA^V, known as monosodium methane arsenate, is registered for use as a herbicide at sod farms, golf courses, highway rights of way, and cotton fields. It has occasionally been associated with accidental or

deliberate ingestion that results primarily in gastroenteritis that is relatively minor compared to the intoxication that appears after similar doses of inorganic arsenic [24, 25]. Many marine organisms and a few terrestrial biota (principally fungi) biosynthesize the trimethylated arsenic compounds arsenocholine and arsenobetaine $[(\text{CH}_3)_3\text{As}^+\text{CH}_2\text{CO}_2^-]$. The latter, an amino acid analogue, exists in dietary seafood at concentrations ranging from approximately 1–100 ppm but appears not to be metabolized after ingestion and exerts no known toxicity. Arsenosugars and arsenolipids occur in edible marine organisms and certain plants; although arsenosugars are partially metabolized to DMA, they are not associated with acute human toxicity. The occurrence and chemistry of organoarsenicals in the diet have been reviewed [26].

Trivalent and pentavalent arylarsenical antibiotics (e.g., arsphenamine and carbarsone) were used widely to treat spirochetal and protozoal infections in the first half of the twentieth century. Today the only organoarsenical manufactured as a

human pharmaceutical is melarsoprol, reserved for the treatment of the meningoencephalitic stage of African trypanosomiasis. Pentavalent arylarsenicals, such as roxarsone (4-hydroxy-3-nitrophenylarsonic acid), sodium arsanilate, and nitarsone, were formerly used as growth-promoting feed additives or antibiotics for poultry and swine, but as of 2016 all arsenic-containing drugs have been withdrawn from use in food producing animals in the United States.

Arsine

Arsine (AsH_3) is an extremely toxic colorless gas with a density heavier than air. In contrast to the other arsenicals, which principally result in acute toxicity after ingestion of a sufficiently large dose, arsine gas is an acute inhalational hazard. Arsine gas is liberated when any inorganic arsenic-containing material comes in contact with nascent hydrogen. Severe accidental poisonings have occurred when metal ores, alloys, or metallic objects (particularly objects made of aluminum or zinc) have come in contact with acidic (or occasionally alkaline) solutions, producing arsine gas from arsenic impurities in the metal or the solution or both [27]. As discussed subsequently, arsine poisoning is distinguished from other forms of arsenic intoxication by its characteristic production of intravascular hemolysis.

Lewisite

The chemical warfare agent lewisite (dichloro [2-chlorovinyl] arsine ClCH:CHAsCl_2), named after Lewis, its American inventor, a chemist, is a volatile vesicant liquid that causes immediate severe irritation and necrosis to the eyes, skin, and airways. The median lethal dosage by inhalation is 1200–1500 mg-min/ m^3 ; eye injury occurs at dosages less than 300 mg-min/ m^3 [28]. In recent decades, rare but significant accidental exposure to lewisite from old munitions has occurred. A current review of the acute and chronic effects of lewisite is available [29].

Pathophysiology

Arsenic

The acute and chronic noncancer toxicity of arsenic is a consequence of a multitude of interactions with cellular proteins, cofactors, and nucleic acids. Arsenite combines with the sulfhydryl groups of enzymes and cofactors, such as the vicinal dithiol lipoate component of the α -keto acid oxidation systems, that are vital to the main oxidative pathways of the tricarboxylic acid cycle [30]. In particular, arsenite has long been known to inhibit strongly pyruvate dehydrogenase [31], and more recently MMA^{III} has been shown to be even more potent in this regard [19]. Arsenite and to a greater extent MMA^{III} are potent inhibitors of enzymes necessary for cellular protection against oxidative stress, such as glutathione reductase and thioredoxin reductase [32, 33]. Arsenite exposure *in vitro* is associated with oxyradical production, mutagenesis, and cell death [34]. Arsenate and pentavalent methylarsenicals are reduced *in vivo* to trivalent species [26], which subsequently may bind proteins, interfere with enzymatic function, or increase oxidative stress. Arsenate also may impair cellular energy production through unstable substitution for phosphate in phosphorylation reactions, resulting in cellular depletion of adenosine triphosphate [35]. Inorganic arsenic may interfere with heme biosynthesis, reflected in part by elevated excretion of urinary porphyrins [36].

In addition to the aforementioned effects, inorganic arsenic or its methylated metabolites are associated with numerous other cellular perturbations, such as alterations in gene expression, cell-cycle regulation, signal transduction, and apoptosis, that may contribute to acute and chronic cancer and noncancer effects [37]. Arsenite induces DNA-protein cross-links [38] and interferes with microtubule assembly [39]. Arsenic has been associated with chromosomal aberrations in multiple *in vitro* and *in vivo* studies, and one investigation has suggested that trivalent methylated arsenicals may damage DNA directly [20]. The numerous cellular effects induced by arsenic in

experimental studies often depend on the intensity and duration of arsenic exposure, and the precise mode of action responsible for the spectrum of clinical effects of arsenic has not been elucidated. The fact that the biochemical targets of arsenic are ubiquitous in cells throughout the body is consistent, however, with the fundamental clinical observation that the effects of arsenic typically are multisystemic in their presentation.

Humans seem to be more susceptible than experimental animals to the toxic effects of inorganic arsenic. The median lethal dose of arsenite in hamsters is 8.5 mg/kg [19] and ranges from 15 to 75 mg/kg in mice and rats [2]. By comparison, potentially lethal complications have been observed in adult humans after the acute ingestion of approximately 200–300 mg (3–4 mg/kg) of a soluble form of inorganic arsenic.

Arsine

Arsine gas is a potent hemolytic agent. In vitro studies with human erythrocytes suggest that a large increase in intracellular calcium associated with an alteration in membrane sulfhydryl groups is a key feature of the hemolytic process [40]. In these experiments, arsine-induced changes in transmembrane ion flux appeared within 5 min of exposure, followed by significant hemolysis at 1 h. The strong susceptibility of erythrocytes to the toxic effects of arsine, but not arsenite, suggests that the hemolysis might be induced by a reaction product of arsine formed in the presence of heme, which is highly abundant in these cells [41]. The pathophysiology of the adverse effects that follow arsine inhalation is multifactorial. The intrarenal deposition of hemoglobin and other cellular debris from lysed erythrocytes may produce acute tubular damage and oliguric renal failure. Severe hemolysis diminishes peripheral oxygen delivery and creates generalized hypoxic stress. Before hemolysis, some arsine is transported via the bloodstream to other tissues [42], which may be damaged by the direct action of arsine or its reaction products. The kidney and possibly other organs convert arsine to arsenite, which further contributes to adverse effects [41, 43].

Clinical Presentation and Life-Threatening Complications

Arsenic

Acute Arsenic Intoxication

The clinical presentation of arsenic intoxication after a single acute ingestion is characterized by multisystemic findings that appear in stages over the course of hours to weeks (Table 1). The most common scenario results from the deliberate or accidental ingestion of several hundred milligrams or more of a soluble arsenic salt. The first stage typically begins 30 min to several hours postingestion, with prominent gastrointestinal distress consisting of nausea, vomiting, abdominal pain, and watery or mucoid diarrhea. There is often abdominal tenderness to palpation. The slightly delayed onset of these gastrointestinal symptoms and their appearance after parenteral arsenic overdose [16] are consistent with an acute mode of action dependent on acute cytotoxicity and increased vascular permeability rather than direct mucosal irritation.

During the initial stage of acute arsenic intoxication, diffuse capillary leak, alone or in combination with gastrointestinal fluid loss, produces cardiovascular signs and symptoms within a matter of hours. In mild-to-moderate cases, there may be thirst, tachycardia, or decreased urine output. More severe cases may result in hypotension, shock, malignant ventricular arrhythmias, and death [44–51]. The oliguria or anuria that occurs during the first 1–2 days after acute arsenic intoxication is most likely a consequence of decreased renal blood flow due to hypotension or diffuse extravascular fluid accumulation, rather than a consequence of acute tubular necrosis. The initial neurologic features of acute arsenic poisoning are highly variable and nonspecific. The mental status may be intact, or there may be lethargy, agitation, or delirium. Generalized convulsions have been reported but are relatively rare [46, 52]. Low-grade fever may be present but is not an invariable finding.

Commonly the initial phase of gastrointestinal symptoms and hypotension stabilizes or improves within 24–48 h but is followed within 1–7 days by

Table 1 Clinical and laboratory findings in acute arsenic poisoning^a

Phase 1: Immediate (within hours postingestion)
Gastrointestinal
Nausea, vomiting, diarrhea, abdominal pain
Cardiovascular
Hypotension (shock), tachycardia, diminished urine output, malignant cardiac arrhythmias
Metabolic acidosis
Rhabdomyolysis
Neurologic
Altered mental status (lethargy or agitation), seizures
Phase 2 (1 day to 1 week postingestion)
Cardiovascular
Prolonged QTc interval, cardiac arrhythmias (torsades de pointes), congestive cardiomyopathy, noncardiogenic pulmonary edema
Neurologic
Encephalopathy (agitation, delirium, stupor, coma)
Renal
Low-grade proteinuria
Hepatic
Elevated hepatic transaminases (slight to moderate), hyperbilirubinemia (slight)
Dermatologic
Desquamation (especially palmar or plantar), maculopapular rash, periorbital edema
Phase 3 (1–4 weeks postingestion)
Hematologic
Anemia, leukopenia, thrombocytopenia, relative eosinophilia, basophilic stippling of erythrocytes, disseminated intravascular coagulation
Neurologic
Sensorimotor peripheral neuropathy, autonomic instability (hypertension, diaphoresis)
Dermatologic
Transverse striate leukonychia (Aldrich-Mees' lines), herpetic lesions (zoster and/or simplex)

^aMore common findings are in **bold** type

a second phase of cardiovascular compromise characterized by mild congestive heart failure, noncardiogenic pulmonary edema, or both. The severity is variable, ranging from mild cardiomegaly or pleural effusions to full-blown acute respiratory distress syndrome [47, 53, 54]. In some cases, the peak manifestations of acute respiratory distress syndrome may be delayed 8–10 days postingestion [55]. The delayed appearance of isolated or recurrent malignant cardiac arrhythmias up to 10 days after an

initial high-dose arsenic ingestion merits particular concern and clinical vigilance. A relatively specific feature is the development of the polymorphic ventricular tachycardia, torsades de pointes. Torsades de pointes frequently is preceded by the common arsenic-associated finding of prolongation of the QT interval, with the QT_c interval frequently greater than 500 ms [56–60]. Sudden cardiac arrest in the absence of QT prolongation or torsades de pointes also may occur within a few days of the initial onset of gastrointestinal symptoms [61].

Patients may exhibit a decline in mental status, characterized by delirium or obtundation, 2–6 days after the onset of acute arsenic poisoning [62–64]. This delayed encephalopathy often resolves spontaneously within a week, but on rare occasions it may persist for a prolonged period [65–67].

A third phase of acute intoxication, generally appearing 1–4 weeks after the initial high-dose ingestion, is heralded by hematologic abnormalities and peripheral neuropathy. The classic hematologic finding is pancytopenia, with the suppression of erythrocytes, leukocytes, and platelets usually reaching a nadir within 1–3 weeks. Complete recovery of all cell lines usually follows within weeks to months. The salient laboratory features are discussed further in the section on diagnosis.

In many but not all cases of acute arsenic intoxication, a symmetric distal sensorimotor axonal peripheral neuropathy evolves 1–5 weeks after the ingestion. Initial findings consist of dysesthesias in the distal extremities in a stocking-glove distribution. Dysesthesias often rapidly progress to “burning” paresthesias, with hyperpathia to mild stimuli, such as bed sheets rubbing against the feet [62, 68]. Other sensory modalities (e.g., proprioception) also are affected, and within days to a week patients experience the onset of motor weakness. The lower extremities may be more affected than the upper extremities in the initial stages. Depending on the severity of the poisoning, sensory and motor deficits ascend symmetrically to involve the proximal musculature, and a marked quadriplegia can occur. In the most severe cases, neuromuscular respiratory

failure requires mechanical ventilation, sometimes for several weeks [53, 69, 70]. Autonomic instability, characterized by episodic diaphoresis, temperature instability, and hypertension, may appear during the peak stages of neuropathy [66]. Although there have been rare reports of visual disturbances [44, 71] and facial nerve paralysis [72], cranial nerve function almost always is well preserved. Signs of slow improvement in the peripheral neuropathy begin to appear within a few weeks after deficits have reached their maximum. The extent of recovery depends on the severity of the peak insult. Patients with mild-to-moderate insults, such as cases with predominantly sensory involvement, have recovered completely, but in patients with severe motor and sensory deficits, distal weakness, wasting, and diminished sensation may persist for years [62, 64, 73].

Several dermatologic signs variably appear after a delay of approximately 1–6 weeks following acute arsenic ingestion. A diffuse maculopapular rash, sometimes with areas of vesiculation, may be noted [55, 74]. Mild-to-moderate desquamation of the skin, mainly in the hands and feet but occasionally in a more diffuse pattern, is common [74–76]. In many cases, the cutaneous reactions have appeared before treatment with chelating agents, which may induce allergic dermal manifestations. Patients may exhibit periorbital edema. Herpetic vesicular lesions, secondary to herpes simplex or herpes zoster, often erupt on the face or trunk days to weeks after substantial arsenic ingestion. This eruption may be triggered by arsenic-related suppression of leukocytes and immune function. Transverse white striae (white bands 1 or 2 mm in width) classically appear on the emerging nail beds of the fingers and toes after 4–6 weeks. Although frequently referred to as *Mees' lines* after the report of Mees [77], this finding of transverse striate leukonychia was described earlier by Aldrich [78] and by Reynolds [79] in arsenic-poisoned patients. The bands, which are thought to reflect an abrupt disruption of keratinization, are not pathognomonic for arsenic poisoning and may occur after other toxic insults, such as thallium poisoning [80]. Multiple bands on the nail

beds may be visible in patients who have had multiple discrete episodes of acute poisoning in the preceding months.

Subacute and Chronic Arsenic Poisoning

Subacute arsenic poisoning shares many of the features of acute arsenic intoxication but is less often life-threatening. The magnitude of the recurrent dose influences the severity and time course of the presentation. A 2–4-month period of consumption of drinking water delivering arsenic doses that were probably on the order of 10–50 mg/day resulted in peripheral neuropathy, sometimes with antecedent gastrointestinal symptoms [81] and sometimes without gastrointestinal symptoms [16]. In a subset of 220 adult patients studied by Mizuta and colleagues [82], 2–3 weeks of ingesting an estimated 3 mg of arsenite per day in contaminated soy sauce resulted in periorbital edema, gastrointestinal symptoms, decreased hematocrit, and mild peripheral neuropathy. During the Manchester beer epidemic of 1900, daily consumption for weeks to months of 1–5 mg of arsenic per day in contaminated beer caused a large outbreak of mild-to-moderate peripheral neuropathy. Hyperpigmentation and periorbital edema commonly were noted. Deaths from congestive heart failure were reported, but the contributory role of alcoholic cardiomyopathy in those cases remains uncertain [79, 83]. Among 104 adults accidentally exposed to an estimated 24 mg of arsenic per day in a lunch meal for 5–8 consecutive days, approximately 80% developed self-limited gastroenteritis and mild-to-moderate elevation in serum alanine aminotransferase, and approximately 70% exhibited leukopenia [84]. Assuming a body weight of 55 kg in that Asian population, the daily ingested dose may have been 0.4 mg/kg.

Experimental trials employing intravenous arsenite in the treatment of refractory or relapsed acute promyelocytic leukemia have provided new insights into the subacute toxicity of inorganic arsenic. The therapeutic mode of action of arsenic in treatment of this malignancy may involve a selective induction of apoptosis in the leukemic cells, possibly through degradation of a specific

oncoprotein [85] or through interaction with the tubulin that is abundant in leukemic cells [39]. Experimental protocols generally have administered 10–20 mg of As_2O_3 intravenously daily for 2 months per course of treatment (an arsenic dose of approximately 0.15 to 0.3 mg/kg/day). Although many subjects have tolerated this regimen, some severe arsenic-related adverse effects have been reported, including arrhythmias, peripheral neuropathy, and hepatotoxicity. Ohnishi and coworkers [86] observed QT prolongation in eight of eight patients receiving daily infusions of 0.15 mg/kg As_2O_3 administered over 2 h, and four of eight patients exhibited nonsustained monomorphic ventricular tachycardia, generally after 3 or more weeks of treatment. Unnikrishnan and associates [87] observed torsades de pointes in 3 of 19 patients, after 42, 16, and 12 days of treatment, respectively. In two of the three cases, the arrhythmia was refractory to treatment, and the patient died. Niu and coworkers [88] observed hepatic transaminase elevation in 7 of 11 newly diagnosed patients entering an arsenite treatment protocol. In five of the patients, hepatic dysfunction was reversible on cessation of treatment, but in two cases it seemed to be progressive. Sensorimotor peripheral neuropathy has occurred 6–8 weeks after initiation of treatment, and nausea, vomiting, and abdominal pain have been common [89].

Chronic arsenic poisoning has been characterized extensively through studies of populations exposed to elevated levels of naturally occurring arsenic in drinking water and through historical accounts of the use of medicinal arsenic (e.g., Fowler's solution) for the treatment of asthma, psoriasis, and other maladies. The adverse effects of chronic arsenic ingestion have been reviewed in detail [26, 37]. Noncancer chronic effects include a distinctive pattern of spotted hyperpigmentation and palmar-plantar hyperkeratosis, hematologic findings of anemia and leukopenia, a sensory predominant axonal peripheral neuropathy, vascular disease, and noncirrhotic periportal hepatic fibrosis and portal hypertension. Nonspecific gastrointestinal complaints, such as diarrhea and cramping, may also occur, but in many instances the cutaneous, neurologic,

vascular, or hematologic effects of chronic arsenic poisoning develop without a history of antecedent gastrointestinal symptoms [90]. Epidemiologic studies have suggested a link between chronic arsenic ingestion and diabetes mellitus, hypertension, and increased cardiovascular disease mortality [26, 37, 91–93]. In the short term (days to months), gastrointestinal, hematologic, and neurologic symptoms may emerge with arsenic doses of 0.05 mg/kg/day. When exposure occurs over several years, noncancer symptoms may emerge at doses of approximately 0.01 mg/kg/day. Chronic arsenic ingestion is well established as a risk factor for lung cancer, bladder cancer, and skin cancer, and occupational studies have identified arsenic inhalation as a cause of lung cancer [26, 37, 94]. Epidemiological studies increasingly link arsenic exposure to an increased risk of certain types of renal cancer [95] and liver cancer [96]. The latency period for arsenic-induced cancers may range from one to four or more decades [97, 98].

Arsine

Although exposure to arsine occurs by inhalation, the gas is nonirritating, and there generally are *no immediate symptoms*. Although a garlic-like odor has sometimes but not invariably been reported, the reported odor threshold of 0.5–1.0 ppm does not provide sufficient warning properties [99]. Most arsine intoxications are associated with acute occupational exposure occurring over 30 min to a few hours. After a typical delay of 2–24 h, patients often report nonspecific constitutional symptoms that may include malaise; headache; fever or chills; and gastrointestinal disturbance, particularly nausea, vomiting, and crampy abdominal pain [100]. In some cases, the pain has occurred predominantly in the low back or flank, rather than the abdomen [101]. Patients also may complain of numbness or coldness of the extremities. In severe exposures, sudden cardiovascular collapse and death may ensue within 1 or 2 h [102]. The clinical features of acute arsine poisoning are summarized in Table 2.

Table 2 Clinical and laboratory features in acute arsine poisoning^a

Constitutional
Malaise, fever or chills , acute sensation of numbness or cold in extremities
Gastrointestinal
Nausea and vomiting, crampy abdominal pain , low back/flank pain, hyperbilirubinemia (slight to moderate)
Hematologic
Hemolysis, elevated plasma hemoglobin
Renal
Hemoglobinuria (dark red urine), oliguria or anuria (active urine sediment [cells and casts; may be delayed], increasing serum creatinine and BUN)
Dermatologic
Bronze discoloration of skin
Neurologic
Headache , altered sensorium (delirium or agitation), delayed sensorimotor peripheral neuropathy

^aMore common findings are in **bold** type

In the absence of rapid fatality, a characteristic finding in the first 2–24 h is the passage of dark, reddish urine, usually followed by oliguria and sometimes anuria [103, 104]. There is often a concomitant appearance of a copper, bronze, or jaundiced discoloration to the skin [105, 106]. The urine discoloration is attributable to hemoglobinuria, and the skin discoloration possibly is due to elevated plasma hemoglobin; both of these effects follow the significant intravascular hemolysis. Oliguria and anuria, which may last days to several weeks, are the hallmark of acute tubular necrosis. Within the first 1–2 days after presentation, a few patients with acute arsine poisoning may develop an altered mental status, ranging from agitation to frank hallucinosis [106, 107]. Electrocardiogram changes during this time may include nonspecific T-wave changes or occasionally peaked T waves [108], but in contrast to the picture in acute inorganic arsenic poisoning (see earlier), significant conduction abnormalities or malignant arrhythmias are uncommon. The delayed appearance (within weeks) of a mild-to-moderate sensorimotor peripheral neuropathy has been reported after acute arsine poisoning [106, 109]. Transverse

white striae of the fingernails, known as *Aldrich-Mees lines*, also may emerge during that time interval.

Chronic arsine poisoning has been described only rarely. Bulmer and colleagues [110] reported chronic arsine poisoning in 14 workers engaged in the cyanide extraction of gold. Five workers with the longest exposures (5–9 months) complained of persistent headache, weakness, shortness of breath, and nausea and vomiting and were noted to have severe anemia. Among the 14 subjects, the degree of anemia was proportional to the length of exposure, but specific exposure levels were not determined. In experimental models, subacute and subchronic exposure of rodents to arsine in the range 0.025–5 ppm has been associated with reversible hematopoietic effects [99].

Diagnosis

Poisoning by Inorganic Arsenic

The diagnostic approach to arsenic poisoning should integrate (1) characteristic signs and symptoms, (2) a history consistent with sufficient exposure, (3) confirmatory laboratory findings, and (4) the relative exclusion of other factors in the differential diagnosis. Acute arsenic poisoning should be suspected in a patient with the abrupt onset of nausea, vomiting, watery diarrhea, abdominal pain, and hypotension, possibly in association with the evolving pattern of cardiovascular, hematologic, and neurologic findings discussed earlier. In symptomatic subacute and chronic poisoning, clinical or laboratory evidence of *multisystemic* adverse effects almost always is present.

Laboratory findings in the initial stage of acute arsenic poisoning often reveal evidence of an elevated anion-gap metabolic acidosis. The initial complete blood count (CBC) may be normal or may reveal an elevated hematocrit due to extravascular fluid loss and hemoconcentration. Rhabdomyolysis may be evidenced by increasing levels of creatinine phosphokinase [111, 112]. The urinalysis may be normal or may reveal low levels of protein or heme. Microscopic

examination of the urine usually lacks the prominent cellularity and sediment of acute tubular necrosis, however. Initially, blood urea nitrogen and serum creatinine may be normal or slightly elevated. These parameters of renal function often increase in the presence of diminishing urine output and shock, sometimes with a disproportionate rise in serum creatinine associated with rhabdomyolysis. The electrocardiogram commonly exhibits sinus tachycardia, sometimes with a prolonged QT_c interval, and nonspecific S-wave and T-wave changes [56, 59].

The chest x-ray in the initial phase of acute arsenic intoxication is generally unremarkable, but over the next several days the chest x-ray may exhibit mild cardiomegaly, pleural effusions, or both. The presence of radiopaque material in the gastrointestinal tract, detected incidentally in the region of the stomach on chest x-ray or in the stomach or small intestine on abdominal x-ray, sometimes may provide a clue to acute arsenic ingestion [49, 113, 114]. The presence of a radiopacity, owing to poorly dissolved arsenic compounds, is neither a sensitive nor a specific diagnostic finding, however.

Liver function tests in acute arsenic poisoning typically reveal slight-to-moderate increases in hepatic transaminases (alanine aminotransferase and aspartate aminotransferase), which may reach several hundred international units per liter within the first days to a week. Moderate hyperbilirubinemia (e.g., 1–3 mg/dL [17–51 µmol/L]) may be present initially or after a delay of several days. More severe elevations in bilirubin have been noted rarely [111], and in two such cases, liver biopsy revealed slight cholestasis and a marked pattern of hepatocellular mitotic figures [115].

Several abnormal hematologic test results usually are present in the second phase of acute arsenic poisoning and in subacute or chronic intoxication. Pancytopenia, particularly anemia and leukopenia, characteristically is evident on the CBC within 1–2 weeks after acute ingestion. The anemia is usually normochromic and normocytic, but megaloblastic changes also have been reported, with the peripheral smear showing regenerative macrocytes [116]. Basophilic

stippling of erythrocytes may be visible on the peripheral smear [117, 118], as may be nucleated red blood cells with karyorrhexis (irregular pyknotic nuclei). Leukopenia is evident as lymphocytopenia and neutropenia, and the differential white blood cell count often reveals a relative eosinophilia. Bone marrow examination typically reveals erythroid karyorrhexis and megaloblastoid dyserythropoiesis in the context of a hypercellular background. Hemostatic disorders have included a prolonged partial thromboplastin time and disseminated intravascular coagulation [16, 45, 51, 55, 119].

The cerebrospinal fluid in the second or third phase of acute arsenic intoxication may be normal, or there may be mild-to-moderate elevations in protein, usually in the range 50–100 mg/dL. Only rarely does the cerebrospinal fluid protein reach a few hundred milligrams per deciliter [62, 69, 71]. Cerebrospinal fluid cellularity classically is absent or scant. Electrodiagnostic studies and nerve biopsies performed to assess arsenic-induced peripheral neuropathy usually reveal distal axonal degeneration, although some investigators have reported that the early stages of acute arsenical polyneuropathy may exhibit features of a segmental demyelinating process [64, 69, 75, 120].

Measurement of urinary arsenic should be obtained for confirmatory diagnosis. Although a 24-h urine collection sometimes yields information of forensic, toxicokinetic, or research interest, a spot urine collection that measures arsenic concentration is usually sufficient for diagnostic purposes. Most clinical laboratories report the result in terms of *total urinary arsenic*. Diagnostic interpretation sometimes requires a more specific assessment of the chemical forms or “species” of arsenic detected, however. Absorption of inorganic arsenate or arsenite by humans results in excretion of arsenate and arsenite, plus the products of *in vivo* biomethylation, principally MMA and DMA. Certain foods of marine origin, including many finfish, shellfish, and algal products, may contain large amounts of nontoxic organoarsenicals, such as arsenobetaine and arsenosugars. After a seafood meal, arsenobetaine may be excreted unchanged in the urine in concentrations

of several hundred to several thousand micrograms (as arsenic) per liter over the next several days. Arsenosugars, abundant in bivalve mollusks and edible seaweed (e.g., kelp, nori, laver), are metabolized at least partially to DMA [121]. A few types of edible seaweed, notably Hijiki and Laminaria, have been found to contain inorganic arsenate at concentrations of approximately 50 ppm. Regular consumption could result in a daily dose on the order of 100 micrograms that is associated with chronic but not acute health risk [122]. After ingestion of clams or mussels or edible seaweed, the DMA concentration of the urine may be increased to several hundred micrograms per liter. The arsenobetaine and DMA excreted after seafood ingestion is included in the laboratory measurement of total urine arsenic. In North Americans and Europeans with average, “background” exposure to arsenic, the sum of inorganic arsenic (arsenate and arsenite), MMA, and DMA in the urine is generally less than 20 µg/L [26, 123].

Because of the potential presence of large amounts of seafood-derived arsenic in a patient’s diet, the following approach is recommended when ordering urinary arsenic measurement on a potentially poisoned patient. If readily available, a speciated urine arsenic result that reports the concentration of inorganic arsenic (arsenite plus arsenate), MMA, and DMA should be requested. (It may be technically difficult, and not clinically necessary, for the laboratory to differentiate between arsenite and arsenate.) If only a total urinary arsenic measurement is readily available, this should be obtained, but a separate aliquot of the urine should be stored at -4°F (-20°C). If the total urine arsenic concentration is elevated significantly above background values (e.g., $>50\text{ }\mu\text{g/L}$), the retained aliquot should be sent to a toxicologic laboratory that can report the amount of inorganic arsenic, MMA, and DMA present. This practice reduces the potential for a total urine arsenic concentration that is elevated on the basis of recent arsenobetaine ingestion in seafood to be misinterpreted as evidence of recent overexposure to inorganic arsenic. Because DMA derived from arsenosugars in seafood still may appear in the urine in large amounts for 3 days

[121, 124], it nonetheless is important to obtain and consider a careful history of any recent seafood ingestion. If relevant, a follow-up urine specimen obtained after 3 or 4 days of strict abstinence from any seafood should be submitted for speciated arsenic analysis. Urine collected for speciated analysis should not be treated with dilute acids to prevent adsorption onto the sample container because this may alter the speciation profile [125].

In the first 2–3 days after acute, symptomatic arsenic intoxication, the urinary arsenic concentration (expressed as a sum of inorganic arsenic, MMA, and DMA) usually exceeds 1000 µg/L, and the urinary arsenic excretion in 24 h is typically greater than several thousand micrograms. Depending on the severity of the poisoning, the urine arsenic concentration may not return to background levels (total urine arsenic concentration $<50\text{ }\mu\text{g/L}$) for several weeks. In the initial four hours following therapeutic administration of 10 mg As_2O_3 i.v. to cancer patients, As(III) was the major species excreted in urine; however by 24 h DMA predominated [126]. In patients acutely poisoned by ingestion of hundreds of milligrams to gram quantities of inorganic arsenic, it may take several days to a week for DMA to be the predominant urinary arsenic species [14, 127]. The dose-dependent, temporal change in the pattern of arsenic species in the urine following acute exposure indicates that sequential examination of speciated analyses (inorganic arsenic, MMA, and DMA) from an experienced reference laboratory may offer useful clinical and forensic information.

Blood arsenic values are seldom of clinical utility in diagnosis or management for several reasons. Arsenic is cleared rapidly from the blood, and the relationship between symptomatic arsenic intoxication and blood arsenic levels is highly variable and time dependent. Blood values may decline to what some laboratories define as the “normal” range when the urine still contains hundreds of micrograms of arsenic per liter and the patient remains symptomatic. Blood arsenic also is technically more difficult to measure accurately, and speciation, while possible [4], is seldom available. Measurement of blood arsenic

concentration should be reserved for cases when a urine arsenic measurement cannot be obtained, such as an anuric patient. Background levels of arsenic in whole blood usually are less than 5 µg/L (0.07 µmol/L) [26]. In acutely poisoned patients, values greater than 100 µg/L (1.3 µmol/L) (serum or whole blood) have been reported [44, 54, 67, 70, 119, 128].

Arsenic is incorporated from the circulation into fingernails, toenails, and the growing hair shaft at the root. As the hair and nails grow outward, portions that were formed during the time of increased circulating arsenic contain elevated arsenic concentrations. Scalp hair grows at the approximate rate of 1 cm/month [129, 130], fingernails grow at the approximate rate of 4–5 mm/month [10], and toenails grow at the approximate rate of 1.1 mm/month [131]. As a consequence, segmental analysis of hair shafts (e.g., analysis of longitudinally aligned hairs cut into centimeter or subcentimeter sections) or analysis of distal toenail or fingernail clippings may reveal evidence of increased arsenic exposure that occurred months earlier. Because arsenic levels in the urine generally return to baseline levels within a matter of weeks, the elevated arsenic levels remaining in hair or nails may yield important forensic evidence of past exposure. Arsenic can bind to hair and nails from external contamination, however, in a manner that is indistinguishable from that present as a result of internal incorporation. Some data also suggest that arsenic extruded in the sweat during acute poisoning may contaminate distal segments of the hair and nail that were formed long before the arsenic exposure occurred [10, 132]. Thus, the information obtained from analysis of the arsenic content of the hair and nails should be interpreted cautiously [133]. Background levels of arsenic in hair and nails are less than 1 ppm.

The differential diagnosis of acute arsenic intoxication includes other causes of multisystemic illness and organ dysfunction. Many clinical illnesses and poisonings can manifest with the severe gastrointestinal symptoms, hypotension, and metabolic acidosis that are typical of the initial stage of acute arsenic intoxication; examples include bacterial and viral

gastroenteritis, naturally occurring food toxins (e.g., bacterial food poisoning), salicylate overdose, and iron overdose. Acute colchicine overdose may result in acute gastrointestinal distress and hypotension, followed within days by cardiovascular disturbances, altered mental status, and delayed bone marrow depression.

When the early symptoms of acute arsenic poisoning are followed by delayed peripheral neuropathy, the differential diagnosis shifts to several other entities. Guillain-Barré syndrome often occurs as an ascending polyradiculopathy in a patient with a history of an antecedent gastrointestinal illness. In contrast to Guillain-Barré syndrome, arsenical polyneuropathy features prominent early sensory deficits, absence of cranial nerve involvement, and generally lower cerebrospinal fluid protein levels. Noting that some of the early electrodiagnostic features of Guillain-Barré syndrome and arsenic polyneuropathy may be difficult to distinguish, Goddard and associates [134] recommended examination of the proximal F-loop latency, which is prolonged in Guillain-Barré syndrome but not in arsenic poisoning.

Thallium poisoning shares many of the features of arsenic poisoning, including marked initial gastroenteritis, central nervous system dysfunction, and cardiac toxicity, followed by painful peripheral neuropathy and Mees' lines on the nails. In contrast to arsenic poisoning, thallium poisoning does not cause prominent hematologic abnormalities, and it is more likely than arsenic poisoning to produce alopecia.

Patients presenting with alcoholic peripheral neuropathy can have histories of antecedent gastrointestinal distress, anemia, cardiac abnormalities, and liver dysfunction. Compared with arsenic peripheral neuropathy, alcoholic peripheral neuropathy has a slower tempo and may have less prominent motor involvement.

Patients with acute intermittent porphyria may present with a history of abdominal pain, central nervous system disturbance, and peripheral neuropathy, but the condition lacks the prominent sensory involvement of arsenic poisoning. Because acute intermittent porphyria is a genetic disease, it is often associated with a past history of recurrent attacks in adults. Certain nutritional

deficiency syndromes, such as pellagra (dermatologic changes, gastrointestinal symptoms, peripheral neuropathy) and beriberi (mental status changes, cardiac failure, peripheral neuropathy), may share some features of arsenic intoxication.

The following two case summaries (of patients for whom the author provided consultation later in their courses) illustrate some classic clinical features of acute arsenic poisoning.

Case 1

A 39-year-old woman presented to the emergency department complaining of 3 days of nausea, vomiting, diarrhea, and intermittent abdominal pain. Aside from her anxious and bizarre affect, physical examination was unremarkable. On laboratory testing, CBC and electrolytes were remarkable only for a hematocrit of 34% and a serum potassium of 2.8 mEq/L. She was administered 500 mL of intravenous fluids, given a prescription for prochlorperazine, and discharged with a presumptive diagnosis of viral gastroenteritis. She returned the next day with identical complaints. Physical examination remained unremarkable with the exception of a mild postural tachycardia. Laboratory testing revealed electrolytes (in mEq/L) of sodium 134, potassium 3, chloride 107, and bicarbonate 21; serum chemistry panel was remarkable for abnormal liver function tests, with total bilirubin of 1.9 mg/dL [32.5 μ mol/L] (direct 0.3 mg/dL [5.1 μ mol/L]) (reference range for total bilirubin 0.2–1.2 mg/dL [3.4–20.5 μ mol/L], aspartate aminotransferase of 194 IU/L (reference range 5–35 IU/L), and alanine aminotransferase of 225 IU/L (reference range 5–35 IU/L). Serum β -human chorionic gonadotropin was negative. The diagnostic impression remained viral gastroenteritis, with inadequate oral intake at home. The patient was admitted to the medical ward for hydration. Past medical history was unremarkable.

During the first 3 hospital days, intermittent crampy abdominal pain, nausea, vomiting, and diarrhea continued. The patient remained afebrile. On hospital day 4, hematocrit was 28.7%, and white blood cell (WBC) count was 4900/mm³. Urinalysis revealed 2+ proteinuria. Stool cultures and ova and parasite examination were negative.

Slowly progressive periorbital and pedal edema, unresponsive to furosemide, were noted. The patient complained of a dry mouth, and a faint malar rash was observed. On hospital day 7, the patient complained of lightheadedness, and an electrocardiogram revealed supraventricular tachycardia. She was transferred to the cardiac care unit, where additional monitoring over the next 2 days revealed frequent runs of nonsustained polymorphic ventricular tachycardia, including an episode of torsades de pointes. Chest x-ray revealed slight cardiomegaly and small bilateral pleural effusions.

Gastrointestinal complaints resolved by the second week of hospitalization. Aspartate aminotransferase peaked at 542 IU/L on day 7. CBC revealed slowly progressive pancytopenia, reaching a nadir on day 10 with hematocrit 22% and WBC count 1100/mm³. A bone marrow biopsy specimen showed erythroid hyperplasia and karyorrhexis; later, basophilic stippling and reticulocytosis appeared in the peripheral blood smear. A prodigious number of additional tests recommended by multiple consultants were essentially negative; the diagnosis of arsenic poisoning came to light with a blood arsenic level of 160 μ g/L (2.1 μ mol/L) on hospital day 11. Repeat testing on day 16 yielded a blood arsenic level of 3 μ g/L (0.04 μ mol/L), and on day 17, a 24-h urine arsenic collection contained 2279 μ g (urine arsenic concentration was 426 μ g/L [5/7 μ mol/L]).

Palmar desquamation was observed on day 23. A progressive sensorimotor peripheral neuropathy first became evident on day 30. Weakness progressed proximally, and on day 46, neuromuscular respiratory failure necessitated intubation and mechanical ventilation. Cranial nerves were intact. Head computed tomography scan and electroencephalogram were normal. Lumbar puncture revealed acellular fluid with a protein of 121 mg/dL. Seven to 10 days of autonomic instability, characterized by transient episodes of hypertension (systolic blood pressure 140–210 mmHg), tachycardia (140 beats/min), and diaphoresis, appeared to respond to metoprolol. By day 62, motor strength began to return in a proximal-to-distal direction, and on day 73, the patient was weaned successfully from the ventilator. Gross

voluntary limb movement returned on day 83. Six months after the acute poisoning incident, the patient had recovered most motor strength in the upper extremities and proximal lower extremities, but residual weakness remained in the toes.

Comment: The source of the arsenic poisoning was never detected, but foul play was suspected. Because the initial attempt to investigate heavy metal poisoning was performed with a blood arsenic measurement, the diagnosis was almost missed. Although the blood arsenic level still was elevated on day 11, it had returned to normal range by day 16, a day before the preferred test, urine arsenic concentration, remained markedly elevated. The patient received 3 days of chelation with intramuscular dimercaprol (British antilewisite [BAL]) from day 17 to day 19, which did not avert the subsequent development of peripheral neuropathy (see later under Treatment).

Case 2

A 27-year-old man self-injected approximately 0.6 mL of an arsenic-containing herbicide (arsenite dose 330 mg) in a suicide gesture. He presented to the emergency department 30–60 min later with an alert mental status and profuse vomiting. Vital signs included blood pressure 104/50 mmHg, pulse 103 beats/min, temperature 98 °F (37 °C), and respiratory rate 40 breaths/min. Physical examination was normal except for slight diffuse erythema. Initial laboratory tests revealed an anion gap acidosis with serum electrolytes (mEq/L) of sodium 141, potassium 2.8, chloride 106, and bicarbonate 14 and an arterial blood gas on 6 L/min oxygen of pH 7.57, PCO₂ 14 mmHg, and PO₂ 156 mmHg. CBC included hematocrit 45.2%, WBC count 6000/mm³, and platelets 257,000/mm³. Prothrombin time was 11.7 s. Prompt chelation with dimercaprol, 300 mg intramuscularly every 4 h (approximately 4 mg/kg every 4 h), was begun 10 min after presentation. The patient became transiently delirious over the next 12 h. A spot urine arsenic concentration on admission was 13,100 µg/L (174 µmol/L), and a 24-h urine collected between the second and third day contained 11,396 µg of arsenic. Vomiting subsided within 36 h. Transient oliguria that developed 24–48 h

postadmission was accompanied by a rise in serum creatinine from 1.6 mg/dL [141.4 µmol/L] to 2.1 mg/dL [185.6 µmol/L]. Urine output increased, however, with vigorous fluid hydration, and serum creatinine decreased to 1.0 mg/dL [88.4 µmol/L] on day 4.

A progressive thrombocytopenia developed during the first 6 days, with platelet count declining to 66,000/mm³. Fibrinogen was 175 mg/dL (5.15 µmol/L) (reference range 200–400 mg/dL; 5.88–11.8 µmol/L), and fibrin split products were increased slightly, leading to an impression of low-level disseminated intravascular coagulation. The patient developed episodic disorientation and hallucinations on day 6 and became markedly tachypneic. Dimercaprol was discontinued. Urine arsenic excretion on day 7 was 9623 µg/24 h. Chelation with oral succimer, 800 mg every 8 h (10 mg/kg three times a day), was begun on day 8, and the platelet count subsequently increased over the next 2 days to 137,000/mm³. The hematocrit decreased to 28%, however, and the WBC count reached a nadir of 3700/mm³. On day 10, there was an episode of ventricular tachycardia, and the chest x-ray after intubation revealed patchy bilateral infiltrates consistent with adult respiratory distress syndrome. Invasive hemodynamic monitoring revealed high-output congestive heart failure. Succimer was continued via a nasogastric tube. On day 14, cardiopulmonary and mental status improved, and the patient was extubated. On day 17, there was abrupt onset of a progressive sensorimotor peripheral neuropathy. Succimer dose was decreased to 250 mg three times a day on day 20 (when urine arsenic excretion was 992 µg/24 h) and was continued through day 48 (when urine arsenic excretion was 129 µg/24 h). The peripheral neuropathy advanced to quadriplegia by day 59. Slow improvement in limb strength began on day 64, and the patient was able to stand with the assistance of ankle braces by day 96.

Comment: In this rare case of intravenous arsenic overdose, the patient developed initial vomiting and intravascular volume depletion, followed more than 1 week later by life-threatening cardiopulmonary complications and delirium. These complications occurred despite

the prompt initiation of chelation with intramuscular dimercaprol. Thrombocytopenia and low-level disseminated intravascular coagulation, which necessitated discontinuation of dimercaprol, coincidentally resolved when the chelation regimen was changed to oral succimer. A delayed sensorimotor peripheral neuropathy still ensued.

Poisoning by Arsenic

Arsenic poisoning should be suspected strongly in a patient with a history of premonitory constitutional complaints and gastrointestinal disturbance, notably cramping abdominal pain, which is followed within hours by passage of declining volumes of reddish urine and the development of a coppery or jaundiced discoloration to the skin. A history of recent work in which acidic solutions have come in contact with metallic ores or slag is highly suggestive of exposure but is neither specific nor essential.

Common laboratory tests almost always reveal a pattern of evolving, severe hemolysis. The urine is usually heme positive on dip-stick, but microscopic examination may be devoid of formed red blood cells in the initial hours. As oliguria develops, the scant urine usually is strongly dip-stick positive for heme and positive for protein, and microscopic examination reveals an active sediment with red blood cells, red blood cell casts, or granular casts. The urine hemoglobin level should be assessed quantitatively: It may be approach 3 g/L with significant hemolysis, and values ultimately may exceed 10 g/L [105, 135].

In the first few hours after acute overexposure, the CBC may reveal a hematocrit or hemoglobin that is normal or only moderately decreased, but within approximately 12–36 h these values may decline dramatically, with hematocrits in the 20s and hemoglobin values in the range 5–10 g/dL (50–100 g/L). Measurement of plasma or serum hemoglobin should be obtained because elevations greater than 1.5 g/dL (>15 g/L) are common in clinically significant arsenic poisonings and may have prognostic significance. Plasma or serum hemoglobin initially rises, then remains elevated

during the course of active hemolysis, which may persist for several days in the absence of treatment by exchange transfusion (see later). Erythrocyte morphology may include characteristic “ghost cells,” which appear as an enlarged membrane enclosing a pale or vacant interior [101, 102, 106]. Erythrocyte fragmentation, spherocytes, and acanthocytes variably may be found. Leukocytosis is common, and reticulocytosis may appear within a few days. Coombs’ test is negative.

Serum chemistries often reveal mild-to-moderate elevations in total bilirubin (e.g., 2–5 mg/dL [34.2–85.5 μ mol/L]) within the initial 48 h. Although the skin discoloration of arsenic-poisoned patients sometimes has been described as “jaundiced,” the typical elevation in serum bilirubin is inadequate to account for the dermal appearance. Plasma hemoglobin or degenerated heme products instead may be responsible. Serum transaminases may be slightly elevated, but lactate dehydrogenase typically is markedly elevated, consistent with the hemolytic state. Blood urea nitrogen and serum creatinine increase as acute tubular necrosis proceeds and renal output declines. As with most cases of acute tubular necrosis, the acute renal insufficiency of arsenic poisoning generally is reversible after days to weeks of supportive care, although some residual insufficiency may persist.

Blood and urine arsenic concentrations are elevated in symptomatic arsenic poisoning, but the range of values reported in the literature for similarly affected patients is extremely variable. This variability may reflect differences in the timing of collections, renal function, the impact of treatment, and laboratory precision. The total arsenic concentration in whole blood in severely affected patients has been reported to range from a few hundred to a few thousand micrograms per liter, and total urinary arsenic has ranged from a few hundred micrograms per liter to several thousand micrograms per liter. In one of the only reports of speciated urine arsenic measurements after acute arsenic poisoning, marked elevations of inorganic arsenic and its methylated metabolites were detected, with the latter increasing in preponderance over 5 days [136]. Although total (and potentially speciated) urine arsenic levels and total whole-blood arsenic

Table 3 Treatment of acute arsine poisoning

Supportive Care
In patients with evidence of hemolysis (especially plasma hemoglobin ≥ 1.5 g/dL [≥ 15 g/L]), perform exchange transfusion with whole blood
Maintain vigorous urine output with intravenous fluids and mannitol (osmotic diuresis)
Perform hemodialysis as needed for progressive renal insufficiency
Chelation
Currently available chelating agents are of uncertain benefit in arsine poisoning (see text)
In first 24 h, BAL may be beneficial: 3.0–5.0 mg/kg intramuscularly every 4–6 h
Beyond first 24 h, DMPS (oral or parenteral) or DMSA (oral) in patients with evidence of severe intoxication may offer some clinical benefit.
<i>DMPS</i> dimercaptopropanesulfonic acid or unithiol, <i>DMSA</i> dimercaptosuccinic acid or succimer

levels should be ordered for confirmatory or forensic purposes, the diagnosis usually can be established by the history, the clinical picture, and the pattern of common laboratory tests (urinalysis, CBC, and serum chemistries). In any case, the prompt and often intensive supportive care (Table 3) required in acute arsine poisoning should not be delayed pending the return of arsenic analyses. If industrial hygiene data on the patient's actual or estimated arsine exposure are available, this may help to confirm the diagnosis. The acute exposure guideline levels (AEGL) for arsine developed by the U.S. National Research Council [99] reported that disabling effects (AEGL-2) might result from 30 min of exposure to equal to or greater than 0.21 ppm, 1 h of exposure to equal to or greater than 0.17 ppm, or 8 h of exposure to equal to or greater than 0.02 ppm. Life-threatening or lethal effects (AEGL-3) could result from 30 min of exposure to equal to or greater than 0.63 ppm, 4 h of exposure to equal to or greater than 0.13 ppm, or 8 h of exposure to equal to or greater than 0.06 ppm. No toxicity or systemic arsenic absorption was observed in a hairless mouse model involving exclusive dermal exposure to 300 ppm arsine for 5 min, suggesting that percutaneous absorption will not pose a risk to workers or first responders with adequate respiratory protection [137].
